The right side furnished a slightly adhering and easily detached ovarian cyst the size of a very large kidney, which had a pedicle easily ligated and divided. The uterus had attached to its fundus a fibroid tumor the size of a fist, and it was amputated at the level of the internal os in the manner originated by Dr. John Homans. The broad ligaments were tied off as low as possible with two ligatures on each side, one inch apart, care being taken to avoid the bladder; and the broad ligament was divided on both sides between the ligatures; then peritoneal flaps before and behind were made and reflected back. The uterine arteries were ligated by the aid of an aneurism needle; the uterus was divided by a V-shaped cut, forming anterior and posterior flaps, which were brought together over the stump.

The abdominal cavity was flushed out; the incision was sewed up; gauze and rubber tube were used for drainage, extending from the fossa of Douglas to the lower end of the incision.

A hand-to-hand fight with shock in which figured brandy, strychnine, digitalis, nitroglycerin, and oxygen, followed for twenty-four hours, after which the patient rallied and made a steady and complete recovery. The drainage was gradually removed, and the patient was up in four weeks, and in six weeks went East for the summer.

November, 1896. Patient has gained twenty pounds, and is in perfect health.

#### EXTRA-GENITAL CHANCROID.

KREFTING (*Norsk Magazin for Lægevidenskab*, 1896) records seven cases of extra-genital chancroid. These cases were due to

autoinoculation from a genital ulcer, were placed over the sternum, the back of the hand, right thumb, right side of the breast, the left middle finger, and the left forearm.

Diagnosis was confirmed by microscopic examination.

The seventh patient exhibited only a soft chancre on the right index and had no history of venereal ulcer.

Diagnosis was confirmed by autoinoculation and finding the microbe.

Fournier states that soft chancre of the head is moderate in extent, superficial, solitary, and quickly heals.

Diagnosis can be made only by autoinoculation.—*Monatshefte für Praktische Dermatologie*, bd. xxiv, No. 1.

#### THE OPERATIVE TREATMENT OF CANCER OF THE RECTUM.

TAYLOR (*Annals of Surgery*, vol. xxv, No. 4) summarizes as follows his contribution to this special branch of surgery:

1. Great care should be exercised in the selection of cases for operation. Cancers which have exceeded the limits of the bowel and have acquired adhesions to neighboring parts had better be left alone.

2. The preparatory treatment deserves our utmost attention, having as its object the improvement of the patient's general condition, and as great a degree of intestinal asepsis as it is possible to obtain.

3. Free purgation, intestinal antiseptics, and rectal irrigation cannot have a really useful effect so long as there exists an ulcerating cancerous surface swarming with virulent micro-organisms. The use of the curette whenever possible, followed by irrigation, should accompany the other measures.

4. A preliminary colotomy can scarcely be recommended as a matter of routine. It appears to be chiefly indicated when attempts to empty the intestine and cleanse it have either been impossible or attended with difficulty.

5. We should consider a certain number of types of rectal cancer, both as regards their site and extent, with a view to determining the methods best suited for their removal.

6. Three cardinal rules are suggested as applicable to all cases: (1) Control bleeding as much as possible. (2) Let the principles of aseptic surgery be as strictly observed as the field of operation will admit. (3) Avoid rough manipulations in the separation of the disease; let it be effected for the most part by a process of careful dissection.

7. The perineal operation is best employed for ano-rectal cancers—that is, for cancers which involve the sphincteric zone and extend for some distance above it.

8. If possible, the rectum should not be split in its removal nor should the finger be introduced to serve as a guide in its separation. Elastic ligatures should be applied and sterilized gauze placed beneath before it is cut.

9. Cancers situated in the suprasphincteric region had better be removed by the sacral method. As contrasted with the perineal, it gives more room, bleeding is more easily controlled, separation of the disease is more readily effected, and it gives the best functional results.

10. Temporary sacral resection should not be entirely disregarded, owing to its manifest advantages over the more extensive mutilation of Kraske and Bardenheuer.

11. If, when the cancer is excised, it is found that the upper healthy segment descends easily, an attempt to suture it to the anal margin is worth making, having previously removed the mucous membrane from the lower segment.

12. In cases where the ends of the bowel have been united after removal of the cancerous segment, it is well not to close the sacral wound completely for fear of accidents.

13. For cancers situated high up, as well as for those of wide extent in the rectum, the formation of a sacral anus is often the only means at our disposal.

14. In such cases it appears wise to follow the advice of Gersuny, and give the bowel a twist on its long axis before attaching it to the skin, the object being to establish a modified sphincteric apparatus.

15. The perineo-abdominal and sacro-abdominal operations are grave; they involve serious risks, and can only be required in very exceptional cases. However, we must encourage attempts which help to extend more widely the indications for complete removal of the disease, and such as are suitable for those desperate cases in which the palliative treatment afforded by an artificial anus has hitherto been our only resource.

INDICATIONS FOR THE USE OF THYROID EXTRACT IN GYNECOLOGY AND OBSTETRICS.

CHERON (*Revue Médico-Chirurgicale des Maladies des Femmes*, Dec. 25, 1896) holds that thyroid extract is an excellent remedy

in threatened abortion with hemorrhage, is valuable in preventing the arrest of uterine involution after childbirth, and that it is potent against the premature return of the monthly periods; moreover, it is a valuable galactagogue. Thyroid extract, in other words, stimulates the mammary secretion, while it lessens functional activity of the uterus. In gynecology it has proved valuable in the control of all forms of uterine hemorrhage, whether these be due to tumors or lesions of the adnexa.

It is contraindicated in tuberculosis, since this seems to be stimulated rather than arrested. In heart disease, even though thyroidin is strongly indicated, it should be administered with the utmost care and should be stopped at once upon the first suggestion of tachycardia. Symptoms of thyroid intoxication or tachycardia are oppression, exophthalmos, and irritability. In certain cases the drug produces rapid emaciation. Sometimes gastric vertigo has been observed.

Because of the difficulty experienced in procuring the fresh gland and the repugnance which patients exhibit in digesting it, it is well to administer it in the dry form prepared by druggists. This may be administered in tablets, pastilles, or capsules, in doses of one-twelfth of a grain twice daily before meals. After a month there should be an interval of eight days during which the drug is discontinued, followed by a three weeks' course of the medicine. If indications still exist for its employment a rest of two weeks is given, followed by two weeks of the drug.

---

IMPORTANCE OF PREVENTIVE THERAPEUTICS OF SYPHILIS.

Prof. E. LANG of Vienna ascribes great importance to the prompt arrest of syphilis with preventive therapeutics. In an article in the *Wien. Klin. Rundschau* of January 3 he remarks that internal mercurial medication cannot be prolonged to the necessary extent, owing to injury to the digestive apparatus and the lack of precision in the doses, as it is impossible to determine the exact amount of mercury that passes through the intestines unused. Inunctions have the same disadvantage—the lack of exactness in the dosage and the varying rates of absorption in different people. Subcutaneous injections are therefore more reliable than any other method, and can be graduated to the case. The selection of the preparation is of great importance and requires discrimination, and

it is necessary that the physician should be familiar with the different therapeutic methods. But whatever method is selected, the chief point is to limit the mercury and not administer too much. The mercurialization must be mild. Inunctions and injections with full doses do more harm than good. The eruptions may be postponed, but the later manifestations are inevitably more severe and prove unusually obstinate. A mild preventive mercurial treatment, combined with a rational mode of life and observation of hygienic measures, is one of the most precious therapeutic measures in our possession. The imminent danger of subsequent tabes, which he connects closely with syphilis, renders preventive treatment almost imperative, and the favorable results of mild mercurial therapeutics, especially in his private practice (private patients can be traced much more easily than hospital cases), have impelled him to urge its importance upon all anew.—*Journal of the American Medical Association*, Feb. 20, 1897.

#### NASAL OBSTRUCTION AND THE SYMPTOMS OF CARDIAC DISEASE.

GEORGE ROE LOCKWOOD, in the *New York Medical Journal* of January 16, 1897, concludes a practical paper on nasal obstruction and the symptoms of heart disease as follows:

1. It is highly probable that patients with cardiac disease are more subject than are others to nasal obstruction.

2. Nasal obstruction occurring in a patient with cardiac disease may upset the balance of respiratory compensation and produce decided symptoms.

3. Unless care be taken these symptoms may be mistaken for those of failing compensation, and may lead to a gloomy prognosis and a faulty treatment.

4. Unless the nasal obstruction be properly relieved and the patient allowed a sufficient quantity of good air, the arterial spasm may possibly occur, throwing an increased amount of work on the heart, already handicapped, and may become a factor in inducing dilatation. The effect of the poor quality of the blood thus supplied to the endocardium must also be taken into consideration.

5. Nasal examination made during the day may not reveal the actual obstruction, which is most apt to appear at night when the patient is recumbent and the circulation is in its most sluggish state. To the congestion of the posterior portion of the inferior turbinated

bodies thus induced the characteristic nocturnal attacks are to be ascribed through the medium of asphyxia and arterial contraction. Nasal examination, however, usually reveals extreme vaso-motor irritability of the turbinated bodies.

6. In cases of cardiac disease, including angina and pseudo-angina pectoris, no estimate of the patient's condition can be made and no rational treatment can be inaugurated without a thorough examination of the patency of the upper respiratory passages.

#### THE USE OF INFILTRATION ANESTHESIA.

MEHLER (*Centralblatt für Chirurgie*, No. 9, 1897) has used the infiltration anesthesia in 250 major and minor operations, including herniotomies, laparotomies, resection of ribs, ligatures of vessels, and transplantations. The three solutions he colors with various dyes so that they can be distinguished from each other. He employs a larger syringe than that generally used, and one which can be sterilized by boiling. He is thoroughly satisfied with the method.

It is interesting to note in reference to cocaine anesthesia that Tito Costa has found that employing this solution at a temperature of 120° F. produces immediate anesthesia even in minor concentration (one-half per cent.). For the purpose of testing this method he performed a radical operation for the cure of bilateral hernia. On the left side there was omental hernia. The warm cocaine solution was injected, a little more than half a grain of the drug being employed in all. The patient did not experience the least pain. On the right side there was hernia of the colon. Cold solution of cocaine was employed. Incision of the skin was painful, and nearly twice as much of the drug was employed to produce anesthesia, which even then was not entirely satisfactory. The author has contrived a special apparatus for the purpose of keeping the cocaine at a high temperature. This is practically a water-bath.

#### TWO CASES OF LAPAROTOMY FOR ACUTE INTUSSUSCEPTION.

Dr. J. COLLINS WARREN in the *Boston Medical and Surgical Journal* of February 11, 1897, submits reports of the two following cases as examples of successful treatment of this affection by opening the abdominal cavity and reducing the invagination by taxis. Th-

is now known that the escape of bile into the peritoneal cavity is not of necessity a source of danger. The mechanical irritation caused by its presence may give rise to a serous exudate, but bile is markedly antiseptic in its nature, and many cases have been reported in which bile remained free in the abdominal cavity for days or even weeks without giving rise to peritonitis.

The task, then, which the surgeon is called upon to perform in cases of traumatic injuries of the liver is to check the hemorrhage as soon as possible, and to prevent the retention of bile in the peritoneal cavity on account of its liability to cause cholemia. Various methods have been used to produce this desired result. Rest was, of course, the method earliest employed; later came the era of antiphlogistic treatment with the accompanying vesication and venesection, and to-day one wonders at logic which could support such remedies. Of direct applications compression by means of tamponade was the simplest, most primitive, and quickest method used. Then came the thermo-cautery, and within recent times direct suture of the wound as in other parts of the body. It is to this latter method that Dr. Schlatter especially directs his attention.

The literature on the subject is not very extensive. Postempski, in 1892, reported five cases in which recovery occurred after the wound in the liver had been sutured. Operations by Adler, Smits and Von Eiselberg gave good results with this method. Burkhardt, however, regarded the method of suture as available only in those cases where the wound is a superficial one; if too deep to be included in the track of the needle he advocates the use of iodoform-gauze tampons, so arranged that fibrinous exudate after a few days would form a canal leading to the surface of the abdomen for the escape of bile and wound discharge. Langenbuch performed the operation of fixation of a "wandering liver" by passing a row of sutures through the entire thickness of the right lobe and then fastening them to the cartilages. Adler reported a case of stab-wound of the liver where, in spite of the use of sutures, hemorrhage still continued, and tamponade was finally necessary. Hochenegg, after the removal of a tumor from the liver, preferred to treat the wound extraperitoneally, and supported the upper and lower edges of the wound by sausage-shaped rolls of iodoform gauze, held in place by deep mattress sutures. Von Bergmann removed an adenoma of the

liver and checked the bleeding by drawing the wound together with silk sutures and tying them over strips of iodoform gauze placed along the wound. The sutures were left in place for some days, and finally carefully removed. Korte had a case in which a gunshot wound of the liver was cured by iodoform gauze tamponade of the wound. Other writers cited are divided in their preference between the thermo-cautery and the tamponade with iodoform gauze.

Dr. Schlatter adds to these cases five more of his own. A summary of these is as follows:

1. Stab-wound of the liver; prolapse of the colon and omentum; profuse hemorrhage from the liver; wound about one inch wide and so deep that the finger-tip failed to reach the bottom; two deep sutures of heavy catgut and two capsular sutures of fine silk; recovery.

2. Gunshot (revolver) wound of the liver; severe hemorrhage; three deep sutures of heavy catgut checked the bleeding, and a good recovery was made.

3. Gunshot wound of the liver by Flobert projectile. The track of the bullet involved the stomach, the jejunum, the pancreas, and the left kidney. Patient seventeen years old, and liver tissue was friable. Six deep silk sutures stopped hemorrhage; death after eight hours.

4. Rupture of the liver and right kidney two days before operation; extreme anemia; laparotomy; suture of liver; hemorrhage stopped; saline infusion; death.

5. Almost complete sagittal rupture of the left lobe of the liver. Profuse exudate of bile into peritoneal cavity. Laparotomy and suture of the liver fourteen days after the injury; death.

In only one of these cases (3) was there a tendency of the sutures to cut through the tissues. In this case silk instead of catgut was used, and the tissues were more friable than in the other patients, who were all adults. The results so far as the checking of the hemorrhage from the wounded liver was concerned must be regarded as satisfactory. The combination of deep catgut sutures of large size with fine silk superficial sutures of the capsule is recommended, and will be used by the writer in the future. In view of the success attending the first of these cases the objection of Burkhardt to the use of sutures, in any other than superficial wounds does not appear to be valid.

The fact that it is possible to completely close the abdominal cavity after the use of

sutures in wounds of the liver adds materially to the clinical value of the procedure.

That large bleeding vessels in the parenchyma of the liver may be ligated directly has been shown by Clementi's experiments upon animals, and by Smits's and Von Bergmann's operations.

Where the wound is a large one, as after the removal of a tumor, the combination of sutures, mattress sutures and tamponade may be necessary; but as a rule the tampon should be used only in cases where sutures have failed to check the hemorrhage. Of the three methods the thermo-cautery is of least value; it will check only moderate parenchymatous hemorrhage, is of no value in extensive wounds, and is apt to be followed by secondary hemorrhage.

Another important question remains to be considered in this connection. However summarily the surgeon may act in gunshot or stab-wounds of the liver, there remains a class of cases in which the diagnosis is often very difficult, and the proper course to pursue is uncertain. These are the cases of subcutaneous rupture. Of course, if after a severe injury to the abdomen in the region of the liver there gradually develop the symptoms of internal hemorrhage, if the pulse becomes more rapid and small, and if the patient grows more and more anemic, if the area of liver dulness on percussion is increased, if pain referred to the scapular region develops, or icterus begins to appear, the diagnosis is easy. Unfortunately for physicians, cases where the symptoms are so well marked are very rare. Such violence as is caused by the kick of a horse does not by any means always result in an internal lesion. Fatal cases have been reported of this character where the autopsy revealed an acute peritonitis and no other internal injury. On the other hand, slight accidents may give severe results—for example, the mere fall upon the ice. The cause of rupture of the liver may be an indirect one, as is strikingly shown in a case reported by Rezek, where the victim fell a short distance, striking upon the feet; death was shown to have been caused by a rupture of the liver and of the great vessels at its base. Aside from the size of the organ, the slight elasticity of its tissue, its method of attachment, and its weight, are important factors in the occurrence of rupture.

The symptoms of internal hemorrhage may also easily be confounded with those of shock arising from slight contusions of the abdomen. Changes in the heart or in the brain

will give a similar clinical picture to the one produced by bleeding—thready or absent pulse, deathly pallor, superficial or irregular breathing, and marked mental depression with restlessness. A differential diagnosis in such cases may be impossible, and time only will show the actual condition.

To diagnostic uncertainty must be added the other considerations which add to the surgeon's perplexity. Certain cases of ruptured liver have gone on to a spontaneous recovery without surgical intervention. Even if an operation be performed, the occurrence of liver-cell emboli may set at naught the best efforts, and the more severe and extensive the laceration the more apt is such a misfortune to occur.

In view of these facts would it not be better for the surgeon to sit idly by and allow the patient to await his fate?

To this important question most operators will answer "No," and maintain that it is the duty of the surgeon in such cases to adopt the course that offers the greatest number of chances of success to the patient. If an operation be performed and a slight injury found, there is of course a very slight possibility that spontaneous recovery could have taken place. On the other hand, if the liver is found almost pulpified by the severity of the trauma the patient would die in any case. Between these two extremes lie a great number of cases of varying severity. The decision must be given in favor of an exploratory laparotomy. If occasionally such an operation is performed with no discoverable necessity, the surgeon can at the present time easily justify the procedure as being on the side of safety. How much more will be the censure if he has failed to realize the gravity of the case, and has either operated too late or not at all?

The time of operation is to be determined by the fact that the sooner it is performed the more apt it is to be successful. For the surgeon the only question of doubt is regarding a possible unnecessary operation. With the practicing physician the decision is much easier. If there is the slightest indication that there may be a rupture of the liver, the decision of a surgeon should be at once obtained in order that no valuable time may be lost. The diagnosis will often be cleared up in the meantime, and an operation may be performed with the least possible delay.

The only remaining question to be considered is the one, What portion of the abdominal wall offers the best site for the operative

incision? The upper portion of the liver, hemmed in as it is by the costal framework and by the diaphragm, is in a bad position for surgical access. The left lobe and the irregular and concave under-surface is, on the contrary, most accessible. By moderate traction the anterior portion of the convexity can usually be brought within reach, and in a similar manner even the almost inaccessible posterior parts can occasionally be operated upon. In one case reported above (Case 4) Schlatter was thus able to suture the lobus spigelii. Division of any of the ligaments of the liver, with the possible exception of the suspensory ligament, which is of little or no hindrance to an operation, is scarcely to be contemplated. The use of tension will therefore be of but little assistance in moving the organ to any given site of operation.

In penetrating wounds the existing wound can be enlarged and converted as far as possible into the incisions about to be described. If the site of injury is in the left lobe, or is undetermined, a median incision should be made; in wounds of the right lobe a curved incision along the lower border of the costal cartilages and to the right of the rectus muscle is to be preferred. In some cases these may be combined, thus forming an angular incision. Since by far the greater number of wounds of the liver are located on the ventral or lateral aspects of the viscus, these two plans of attack will nearly always suffice. In wounds situated posteriorly the lumbar incision is hardly to be recommended on account of the thickness of the muscular walls, and the fact should be borne in mind that, as reported by Lannelongue, the thoracic wall can be resected along the anterior portions of the eighth, ninth, tenth, and eleventh costal cartilages, for the pleura does not extend down to this part of the chest-wall. The method of Lannelongue consists in an incision parallel with the thoracic border and two centimeters above the same, beginning three centimeters from the border of the sternum and ending at the junction of the tenth rib with its costal cartilage. The retraction of the divided muscles exposes the costal cartilages to be resected; they are carefully freed from their attachments and cut through with cartilage scissors. Then, if the ends of the ribs are retracted and pressed apart, nearly the entire extent of the convexity of the liver can be made accessible.

It seems probable that if these practical suggestions of Dr. Schlatter are adopted as a basis of treatment, not merely by surgeons

but by the practicing physician as well, the prognosis in injuries of the liver will in the future be much more favorable.—*Annals of Surgery*, April, 1897.

#### THE PATHOLOGY AND THE SURGERY OF INTUSSUSCEPTION.

In the Hunterian lectures delivered recently before the Royal College of Surgeons of England, d'Arcy Power (*British Medical Journal*, Feb. 13, 1897, p. 381) stated that the evidence derived from anatomic, physiologic, pathologic and clinical data renders it legitimate to assert that spontaneous ileocæcal intussusception occurs when the colon is considerably larger than the ileum, and is so unduly movable that it readily allows itself to become invaginated when once the process has begun. This variety of intussusception is essentially an affection of childhood, and such an undue increase in the width of the colon implies either a congenital abnormality or an unduly rapid growth, for at birth the diameter of the large intestine is practically the same as that of the ileum. Such a rapid increase in the width of the large intestine may, perhaps, in some instances render the ileocæcal valve less competent to guard the end of the ileum, because the valve is not capable of very rapid growth if it is to be firm; but this is probably a factor of very rare and subordinate importance. Though anatomic peculiarities are important factors in the production of intussusception, the physiologic factors are no less important, for they apply in all probability to every form of spontaneous invagination, whether it is of the enteric variety, the ileocæcal, or the colic. The physiologic factor is much less easy to specify than the anatomic, for it is almost certainly an individual peculiarity. It may be stated broadly, however, that as regards the ileocæcal portion of the intestine the increased mobility, coupled with the unduly rapid growth in the width of the large intestine, is probably associated with increased and irregular peristaltic movements of the large intestine. Every one who has had much experience in watching children must have noticed how subject they are to an irregular twitching of the muscles, and how greatly such incoordinate movements vary in different children and in different families. They are most common at the instant when the child drops off to sleep and during the act of awakening. They occur both in the voluntary and the involuntary

muscles, and are due, as physiologists think, to a contraction of the interfibrillar sarcoplasm, while the ordinary tetanus and twitch are caused by an additional shortening of the contractile fibres. This theory explains why the symptoms of intussusception so often appear at the instant when a child awakens; why it is that boys rather than girls, and the most active and best-grown children, are attacked as often as those who suffer from chronic inflammatory affections of the alimentary canal. The muscular system in the active and well-grown is undergoing its greatest development, and its sarcoplasm is in as unstable condition as in the puny, in whom the attacks of enteritis have unduly heightened the irritability of the intestinal muscle, and have thus led to the irregular twitchings which, together with suitable anatomic conditions, may form the starting point of spontaneous intussusception. The cause of intussusception is obscure, but clinical evidence shows that it may be produced mechanically, though the spontaneous form is the more common. Among such mechanical causes are direct injury to the belly, sudden and violent muscular efforts, gymnastic movements, jolting or dandling, paroxysmal coughing as in whooping-cough; or it may even be the reward of greediness, as in the cases of some men who were suddenly seized with symptoms of intussusception shortly after eating a quantity of cherries—stones and all. It is indeed no matter of surprise that such causes should produce an intussusception, for any of them might lead to a sudden and limited constriction of the intestine associated with an active peristaltic movement of a neighboring portion sufficient to draw the receiving layer of the gut over the contracted portion, which then becomes the apex of the intussusceptum. As soon as the intussusception has been started, the anatomic peculiarities again become of paramount importance, for they determine the character of the intussusception. In the ileocæcal forms a wide colon, with few and simple ileocolic folds devoid of lymphatic glands, will allow the intussusception to run a chronic course, even though the amount of bowel invagination is very great. Complex fossæ, with numerous glands at the ileocolic angle and prolongations of mesentery along the end of the ileum, will no doubt so far steady the ileum as to render its intussusception less likely; but if it should occur the additional amount of tissue invaginated will

render the impaction so peculiarly tight that, if gangrene is not produced at once, early adhesions will be formed and the intussusception will soon become irreducible—*Medical Record*, April 3, 1897.

#### PNEUMOPEXY.

Prof. C. BAYER, of Prague, states in the *Centralblatt für Chirurgie* of January 16 that he was performing an operation on a thirteen-year-old boy for the extirpation of a large sarcoma of the right thoracic wall, when the pleura adherent to the sarcoma in one place suddenly tore. The laceration was tamponed, when it tore again and the patient began to collapse. The larger tear was sutured, the portion of the sarcoma already detached was removed, and the wound left open, with iodoform dressings. The operation was resumed and completed three days later, when the pleura tore again, and this time the lung collapsed entirely and sank out of sight. The patient was succumbing when Bayer seized the superior lobe of the collapsed lung with a pair of forceps and drew it out of the thoracic cavity through the large hole in the pleura, and fastened its lower border by three sutures about three centimeters apart to the periosteum of the sixth rib, which was immediately above the end of the tear in the pleura. The patient revived at once, and "we saw the upper part of the lung breathing regularly." The inferior lobe remained collapsed, but he refrained from attempting to suture this likewise, as he considered it best to utilize the opening for drainage. The after-results were good. Dyspnea appeared only when the dressings were changed, and he thinks that if he had been able to fasten the inferior lobe also no dyspnea would have occurred. The superior lobe continued its respiration to its full extent, and the lung did not seem to be at all injured by the suture. The patient is now (twenty-seven days after the final operation) recovering finely. The wound is healing perfectly, with a deep depression corresponding to the defect. He considers himself justified in recommending the process of fastening the lung in this way as a simple means to restore this vital organ to its functions, when in cases of extensive injury to the costal pleura it is impossible to put an end to the pneumothorax by merely closing the wound with all haste. It is simpler than the method proposed by Tuffier and Hallion, who have succeeded experimentally in similar cases by artificially filling the lung with a-

through the larynx or trachea. Their experiments on dogs were encouraging, but the operation has not yet been applied to man.—*Journal of the American Medical Association*, Feb. 20, 1897.

AN IDEAL SUTURE FOR THE CLOSING  
OF ABDOMINAL INCISIONS, CUTS  
ON HANDS, FACE, AND BODY  
GENERALLY.

HAUGHEY in the *Journal of the American Medical Association* of February 20, 1897, advocates the following method of suturing abdominal incisions, cuts on the hands, face, and body generally:

The ideal suture is one that, first, can be most readily and easily introduced; second, that holds the parts in perfect apposition with the least possible interference to the circulation of or at the edges of the wound; third, that is the least apt to become septic; fourth, that requires the least possible amount of suture material; fifth, that leaves the least possible scar; sixth, that can be relied upon to fulfil these requirements, and after fulfilling them can be removed.

The old interrupted *en masse* suture, while fulfilling the first requirement of introduction well enough, utterly fails in all the rest except the last, viz. removal; for by including the tissues from one-half to one inch on each side of the wound and tying them the circulation is materially interfered with, thus preventing healing and promoting sepsis by reducing the blood-supply and depriving Nature of its best means of keeping the wound disinfected and promoting its rapid repair.

The buried animal suture is objectionable because of its proneness to become septic despite our very best efforts at cleanliness and antisepsis.

In silkworm-gut and silver wire we find the nearest approach to the ideal suture material that science has yet produced; they can be rendered aseptic, and when so rendered are almost absolutely non-irritating to living tissues. The problem is to so introduce them that they will meet the six requirements above stated. The writer has solved this problem thus: With a straight sharp-pointed needle about one and three-quarters to two inches in length, threaded with silkworm-gut (of the very best variety), he begins at the lower angle of the peritoneal incision on the left side, and with a simple spiral

continuous suture rapidly closes the entire peritoneal cut, bringing the end of the suture out about one and one-half inches above the upper angle of the incision in the skin, passing it through a thin aluminum plate and fastening by means of a perforated shot; then threading the needle on the other end, he brings it out and fastens in the same manner about the same distance below the lower angle of the wound. Do not make too much tension, but fasten just tight enough to avoid a slack suture.

In exactly the same manner introduce the suture in the muscular aponeurosis; here you may, if the cut is long, with advantage use silver wire about No. 23 or 24, as it is probably stronger and can be left as long as necessary with no danger of disintegration, though silkworm-gut may be left in five weeks safely. The skin suture is introduced in the usual manner of a buried skin suture, with the ends fastened as described. It will thus be seen that the first or peritoneal suture will be the longest and will be fastened farthest from the extreme angle of the cut at each end; the muscular suture is second longest and fastened in the centre at each end; the skin suture shortest and fastened nearest the incision at each end.

No difficulty will be experienced in removing either the peritoneal or skin suture if they have been properly introduced; simply grasp the shotted lower end and lay the open blades of the scissors on the aluminum plate, draw on the suture, make contour pressure with the scissors until about one inch of suture is withdrawn; then clip, grasp the other end, and draw the long or remaining end of suture out. The muscular suture will be found to offer in many cases much resistance, and if too strongly pulled on will break. This is not necessary. Simply draw what will come easily and fasten by means of a split shot and wait twenty-four hours, when you can easily draw more; fasten and leave again, and so on until the entire suture is removed.

The author has been using this suture for the past year in cuts, wounds, and operations about the face, hands, or any part of the body. It leaves the least possible scar, offers the least possible interference to circulation, thereby promoting the healing process; can be left indefinitely, can be readily and easily removed, and in fact possesses all the requirements as yet known of an ideal suture. Only the very best, smoothest and strongest silkworm-gut should be used.

*TREATMENT OF FRACTURE OF THE CLAVICLE BY MASSAGE.*

DRAGON (reprint from the *Jour. de Méd. et de Chir. Prat.*) publishes the results of massage applied to twenty cases of fracture of the clavicle, under the care of Lucas-Championnière. The ordinary treatment of this lesion by bandages and slings is held to be unsatisfactory, as it is very difficult by such appliances to keep the fragments at rest and in good position, whilst the functions of the shoulder and elbow are liable to become impaired for some time in consequence of prolonged immobility. The author practices a daily massage not only at the seat of fracture, but also of the adjacent joints and muscles, and insists particularly on massage of the deltoid muscles and careful movements, both active and passive, of the shoulder. In the intervals the upper limb is supported by a sling. Consolidation of a fractured clavicle is usually effected between the eighteenth and twenty-fifth days from the date of injury; and at the end of this period the patient, when treated in the manner described by the author, is able to use the limb freely, as the main object of such treatment is to prevent articular rigidity, and to preserve the full muscular functions.—*British Medical Journal*, March 20, 1897.

*TOO MUCH MAJOR OPERATING IN GYNECOLOGY.*

In these days when the medical profession is devoting so much attention to the major operations on the female pelvic organs, operations looking to the removal of the uterus, ovaries or tubes, or to their fixation in more or less abnormal positions in the body, it is not amiss, in the interests of conservatism at least, that we should pause a little and emphasize certain fundamental principles of gynecology—such as making a careful investigation in every case of the particular points in which the pelvic structures differ from the normal, and then endeavoring to restore them as far as possible to that normal condition.

The medical journals are full of the descriptions of new operations, a vast majority of which have for their object either the removal of organs or an improvement on Nature's handiwork. Operators wish to "build up a perineum," or to stitch the uterus to the abdominal wall or to the bladder. It does not seem to occur to the ingenious originators of these procedures that they

are undertaking a large contract in trying to improve on Nature. Instead of taking a receptive and scientific attitude and trying to search out Nature's methods, they assume knowledge and declare that they can do better.

When a prominent operator advocates "slipping out" a uterus because it is sub-involuted and the seat of endometritis, and another operator is in favor of amputating the cervix as a routine procedure instead of performing trachelorrhaphy, it may be that these practitioners are doing the best that can be done for their patients under the circumstances; at all events it is fair to assume that they think they are doing so. But a large body of the profession will always query, "Why should a woman lose her uterus or have her cervix cut off, with all that these mutilations imply, because the operator finds it easier to remove structures than he does to take the time and trouble necessary for the proper understanding of the more tedious and less brilliant methods of repair?"

When tyros in the art of diagnosis, emboldened by the lessened mortality of the present aseptic technique, rush into major operating the interests of the patient suffer. Many of the hospital operators and teachers help these tyros to a knowledge of the steps of certain operative procedures only to find these same men coming back to them after a longer or shorter period and saying: "Doctor, I know how to do such and such an operation, but I can't tell in what cases it is indicated, and my results have been bad." How much more rational to begin at the beginning!

We believe that the diagnostic skill of the average practitioner in this department of medicine is constantly improving; but to be convinced that there is room for still further improvement the doubter has only to follow for a short time one of the out-patient clinics of a metropolitan hospital and hear there from the patients some of the diagnoses made and treatment advised by a large number of practitioners, all of whom probably are not always incorrectly reported. We are credibly informed that, even now in this enlightened age, a considerable number of patients presenting themselves at our hospital clinics for treatment for injuries of the pelvic organs due to child-bearing tell the old story that their doctors did not examine them after the puerperium. In other words, their medical attendants are pursuing the old policy of trusting to luck, perhaps fearing censure for

injuries<sup>7</sup> discovered, but more likely too busy to do their work thoroughly.

Early recognition of bad tears of the cervix and of the pelvic floor, inflammatory affections of the endometrium and tubes and ovaries, dislocations of the uterus and ovaries that do not right themselves in a reasonable time, if discovered and treated promptly not only do away with the need of many operations but will prevent a large number of patients from becoming debilitated and neurasthenic—conditions of body and mind from which operations alone, be they ever so successful, will not lift them.

We should welcome a return of gynecology to its older and more natural channels. The profession at large, dazzled for the time by the brilliant feats of abdominal surgery, should not forget that gynecology is something besides abdominal surgery; and the general practitioner should be ready to follow the specialist, prepared to investigate and treat the diseases of the female pelvic organs according to well-founded principles of the art. —*Boston Medical and Surgical Journal*, April 1, 1897.

#### THE TREATMENT OF VARICOSE VEINS.

JOHN O'CONOR, in a letter to the *Annals of Surgery* for April, 1897, proposes the following treatment of varicose veins:

After ten years' operative experience the author has come to the conclusion that nothing short of total extirpation of the diseased portion of vein merits the term "radical."

In numerous instances he has performed the orthodox operation—*i.e.*, removal of many bits—and he regrets to say that in a considerable percentage the cure has by no means been permanent.

On referring to one of our most recent standard works, "An American Text-book of Surgical Science," he finds the treatment of this very common complaint is dismissed in some six lines, and he takes the liberty of quoting the following paragraph: "The radical treatment has for its object the complete obliteration of the vein. Many surgical procedures have been devised for this purpose. Of these methods multiple ligature, as advocated by Dr. Charles Phelps, who ties the vein in thirty or forty places, and excision of the vein in six, eight, or more places, are the best." It is needless to mention that neither of these operations can be really described as radical, for complete obliteration does not necessarily follow even forty ligations or the removal of even a dozen pieces.

In the operation that he has practiced for the past year and is about to describe no potential element remains, for the very simple reason that the offending portion of the vessel is removed in its entirety.

The limb having been shaved and disinfected from Poupart's ligament to the ankle, a two-inch incision is made over the saphenous opening, and the internal saphenous trunk is doubly ligated and divided; if no varicosity is present above the knee the wound is closed and dressed at once with iodoform gauze. If the femoral portion is affected, after ligation at saphenous opening, the vein is dissected up and its tributaries seized with pressure-forceps and ligated. In nearly all cases, if varices are present above the knee there are also some below, consequently the incision is prolonged downward directly over the vessel until the lowest limit of the disease is reached; the vein is then tied and divided below. In some cases an eighteen- or twenty-inch incision is necessary.

If the disease does not extend above the knee, after occluding the saphenous trunk as described above an incision is made over the affected portion, a ligature is applied above and below, and the whole mass removed by dissection. It is surprising how easily and rapidly the latter maneuver may be carried out. Of course, all branches are caught up with pressure-forceps, and when the main channel is removed they are ligated. As frequently the external saphenous vein is also affected, its varicose portion is dealt with in a similar manner. To any one unaccustomed to a ten- or twenty-inch incision this plan may appear formidable, yet if the vessel is ligatured above and below the varicose area there is not the slightest danger of emboli or pyemia, and as for hemorrhage it is so trivial that it does not deserve mention. In a recent severe case he removed twenty-six inches of the internal saphenous, and certainly the blood loss did not exceed two ounces. He has also employed this method in removing large thrombosed veins occurring in the first few months of pregnancy; in this class, above all others, it is particularly necessary before manipulating the diseased portion to occlude the main well above the seat of the disease, so that if thrombi are dislodged they cannot pass into the general circulation.

The time occupied in executing this method certainly does not exceed that of any of the nibbling processes. As to primary union, he

finds these long wounds heal just as kindly as do the short ones, and with ordinary surgical cleanliness there is nothing to be feared. The insertion of a strand of iodoform gauze as a drain to every four inches of wound is a useful precaution, for it does away with the risk of any blood collections. Personally, he fears the presence of stagnant blood in wounds more than the germs; where the former is doubtless the latter will gain access.

No bad results have so far followed this method, and all the patients appear grateful.

---

*A CASE OF REUNION OF TENDON NEARLY FIVE YEARS AFTER ITS DIVISION, WITH GOOD RESULTS.*

WORSLEY (*British Medical Journal*, March 20, 1897) presents a case of unique tendon reunion nearly five years after its division.

L. B., a cook, in 1890, when aged thirty, broke a window and cut her right wrist badly. The wound was six weeks in healing, some fragments of glass working out. The thumb, index finger and middle finger afterwards became firmly flexed into the palm. A year after the accident the tendons of the index and middle fingers were cut down upon and reunited by suture, with good result, after long extension on splints; the extension movements of the index finger, however, remained weak and imperfect. In December, 1895, the thumb was strongly adducted and flexed into the palm. The extensor primi internodii and extensor ossis metacarpi pollicis had escaped division, but the extensor secundi internodii pollicis had been cut, and its retracted ends could be obscurely felt in the scar tissue on the radial side of the wrist.

On January 16, 1896, the writer cut down on the scar, having made the limb bloodless, and found the ends of the tendon separated by one and a half inches of fibrous tissue traversing the scar. This band contained in its centre some gelatinous-looking substance, which on microscopic examination proved to consist of a few genuine tendon bundles running through the fibrous material. It was impossible to bring the ends of the true tendon together without splitting them, and to make as strong union as possible an inch only of the fibrous band was excised and the ends were approximated by one stout and two fine silk sutures. Rigid antisepsis was aimed at, and the forearm and hand placed upon a splint, with the thumb overextended on a wire

arm. The wound healed by first intention. There was very severe pain for a long time up the forearm and arm, owing to stretching of the flexors, which had been so long contracted. This pain had prevented continuous extension preliminary to operation. Morphine gave but little relief, and insomnia was troublesome. After a week very gentle passive movement for a minute or two was begun and kept up daily, the thumb being kept overextended on the splint.

Three months after operation the thumb became loosened from the splint in the night, and contracted towards the palm, but not to the former extent. It was secured and always kept on the splint, except when exercised and galvanized daily.

In June, 1896, improvement continued but slowly. If the bandage was taken off the thumb became flexed and adducted to beyond the line of the index finger. Movement in the direction of extension was stronger, however. There was still some pain in the forearm.

In October the patient could leave off the splint for fifteen to twenty minutes, and use the thumb a little. She was advised to take the splint off frequently and exercise the muscles. The current from ten cells was used. On October 27 she wrote a letter, using the thumb. On November 1 the splint was off for three-quarters of an hour, and she had a light steel spring attached to the thumb, riveted to a leather wrist-strap, which exerted a pull equal to three ounces. The tendon could be distinctly felt, with some thickening at the site of union. Since the operation the extensor indicis is much stronger, which is attributable to the disturbance of the adhesions throughout the old scar which then occurred.

At the time of writing—November, 1896—the thumb is practically as good as the other one, except for a little weakness, and the patient will very soon be able to dispense with all artificial support.

---

*APPENDICITIS IN CHILDREN.*

Mlle. GORDON (*Thèse de Paris*, No. 101, 1896-7) deals with this affection on the basis of upwards of eighty cases treated by Broca during a period of three years at the Hôpital Trousseau; seventy have not been previously published. The proportion of boys and girls was nearly three to one (fifty-eight to twenty-one); five were aged between two and five, twenty-five between five and ten, and forty-one between ten and fifteen years. Broca

operated in seventy-two cases with a mortality of thirty-five per cent. The resection of the appendix was performed in thirteen cases after the inflammation had subsided, in all with rapid and complete success; and in five cases during the acute attack, with three deaths. The mortality, including the cases not operated on, was thirty-two per cent. Mlle. Gordon concludes that pathogenesis from a closed cavity is not applicable to the appendicitis of children, in whom calculous or inflammatory obliteration of the appendix is rare; the predominant anatomical lesions are perforation and gangrene. Only two distinct forms of acute appendicitis are to be distinguished clinically—that in which the peritonitis, though purulent, is encysted, and that in which it is generalized. The elective treatment for the former is, in benign cases, resection of the appendix after the inflammation has subsided. When the intervention is one of necessity an inguinal incision or one along the external border of the right rectus should be made, but no search for the appendix. When the case is one of general peritonitis with a local iliac focus, median and lateral laparotomy is indicated.—*British Medical Journal*, March 20, 1897.

**APYRETIC INTRAPERITONEAL RUPTURE OF HYDATIC CYST IN THE LIVER.**

The case described in *La Province Médicale* of December 19, 1896, presented the usual symptoms—sudden pains radiating in the abdomen, syncope, increase in volume of the abdomen, urticaria, vomiting, and slight pleurisy of the right base, but no fever at any time. Professor Jaboulay performed a supra-laparotomy, which gave issue to a large quantity of fluid apparently slightly tinged with bile. The operation was followed by Mikulicz's marsupialization, with strips of iodoform gauze reaching to the cyst in the liver. The discharge of intraperitoneal fluid continued for two months, while the general health and appetite were good. A month and a half after the laparotomy the cyst was punctured and quantities of bile escaped with the hydatid liquid and also fragments of the hydatid membranes. Pieces of the membrane came away for three weeks and were removed with the forceps, when the wound was dressed every day. As the discharge decreased the opening healed, until only a small fistula remains after three months. The presence of bile in the liquid after both

operations shows that there must have been some communication with the biliary passages, and the bile as it entered the cyst must have killed the parasite. The case also illustrates anew the extreme tolerance of the peritoneum for the hydatid liquid and the bile when they are both aseptic.—*Journal of the American Medical Association*, March 20, 1897.

**TO DIFFERENTIATE APPENDICITIS FROM ACUTE CATARRHAL SALPINGITIS.**

VINEBERG notes that the pains are more violent in appendicitis but more strictly localized, without radiating pains, while in catarrhal salpingitis, especially if the ovaries share in the inflammation of the tubes, the pains radiate toward the thigh. The alarming symptoms also show a noticeable remission toward the third or fourth day, which is a useful point in deciding dubious cases, as the alarming symptoms in appendicitis may persist and increase in intensity. If differentiation is impossible the patient should be examined in narcosis. The treatment of appendicitis should be prompt operation, while in salpingitis a waiting policy should be preferred, as it often heals spontaneously without the necessity of an operation.—*Journal of the American Medical Association*, March, 1897.

## Reviews.

TWENTIETH CENTURY PRACTICE: AN INTERNATIONAL ENCYCLOPEDIA OF MODERN MEDICAL SCIENCE. Edited by Thomas L. Stedman, M.D. In 20 volumes. Volume IX: Diseases of the Digestive Organs. New York: William Wood & Co., 1897.

Ten contributors cover the eight hundred and odd pages which compose the ninth volume of this very notable work. Of these ten only four are Americans, namely, Dr. Gibney, New York; Dr. J. B. Murphy, Chicago; Dr. Alfred Stengel, Philadelphia; and Dr. Walker, New York.

The first article, on Diseases of the Mouth, is by Mikulicz and Kümmel. It covers ninety-one pages of the book. The next article, upon Diseases of the Intestines, extends from page 95 to page 271. That upon Hernia covers eighty pages; that upon the Spleen, by Dr. Stengel, covers fifty-six pages; the article on the Liver 350 pages; that upon the Gall-bladder sixty pages; and that upon Movable Kidney about twenty pages. The article upon Diseases of the Intestines is by

Dr. Ewald of Berlin, well known for his work in clinical medicine and by reason of the fact that he is editor of one of the best, if not the best, of the German journals, namely the *Berliner Klinische Wochenschrift*.

Drs. Gibney and Walker contribute the article upon Hernia. The article upon Diseases of the Liver that we have named is written by Semmola and Gioffredi and, as we have pointed out, is the most exhaustive in the volume.

Dr. Murphy contributes the article upon Diseases of the Gall-bladder, and Dr. Franks that upon Movable Kidney. It will be noticed that this volume passes from the consideration of diseases of the mouth to that of the intestines and discusses in no way whatever diseases of the stomach, a subject, however, which has already been thoroughly covered in the tenth volume of this Encyclopedia, which we reviewed some months ago and which appeared in literature prior to Volume IX by reason of unavoidable delays, we presume on the part of foreign contributors.

Volume IX in every way maintains the good opinion which was produced by an inspection of the preceding volumes, and the series is undoubtedly one of the most notable which has appeared for many years.

A SYSTEM OF PRACTICAL THERAPEUTICS. Edited by Hobart A. Hare, M.D. Volume IV. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1897.

Six years ago, when the first two volumes of this System appeared, it was stated that they were designed to present the medical profession with the latest and best views of prominent practitioners as to the proper treatment of the diseases commonly met with by practicing physicians, and the object of this volume, which is complete in itself and yet which forms a supplement to the earlier volume, is well described in the preface which we append:

"The fact that the System of Therapeutics edited by the undersigned met with a most cordial reception on the part of the medical profession indicated that at that time some exhaustive and authoritative representation of practical and modern treatment was needed; and the advances made in this department of medicine have been so great within the last five years that a single volume embodying the present views of the most experienced men in all branches of medicine seems again desirable.

"In the preparation of this volume the Editor has kept in mind the fact that it must bring to each reader the personal methods of its various contributors rather than discuss every plan of treatment which has been introduced, whether it be commonly employed or not.

"Too often works composed of the contributions of many writers vary greatly in the value of the articles and in the professional standing of their authors, and too often these contributors are largely residents of one district and therefore mirror peculiar local views or measures, so that the work fails to convey the results or the methods employed by men meeting with ailments under various climatic conditions. The wide geographical distribution of the authorities who have written these articles prevents any such fault.

"Again, bare suggestions that this drug or that be given in the presence of certain conditions is not what the practicing physician wants. He desires definite directions as to its dosage and its prescription, and he wishes to know how the author himself would use the remedies he commends if he were at the bedside. For this reason a large number of illustrative prescriptions are included in the text.

"The promptness of the various contributors in sending in their articles and the rapid work of the printing office enable the Editor to present the most recent ideas as to rational therapy, and he desires to express his appreciation of the courtesy of his collaborators in this very considerable undertaking."

A HAND-BOOK OF MEDICAL CLIMATOLOGY. By S. Edwin Solly, M.D., F.R.C.S. Illustrated. Philadelphia and New York: Lea Bros. & Co., 1897.

This octavo volume of nearly 500 pages has been written by a physician who for many reasons has devoted the best years of his life to the study of the remedial influences which climate can exercise upon disease, particularly the diseases which affect the respiratory tract. Dr. Solly therefore brings to the author's pen a large amount of original research and practical experience, two attributes which are essential for the successful preparation of a volume which deals on the one hand with the most important remedial measures that we can institute, and on the other with a subject about which we all know comparatively little and many of the profession know nothing. Further than this, the writer has steered his craft of author-

ship safely past the rock of ultrascientific observation on which it might be wrecked for all practical purposes, and has also kept away from an equally disastrous collision with the cliffs of quackery and the danger of transforming an attempted scientific book into a guide-book and advertising medium for health resorts. As it is Dr. Solly has presented us with a clear and lucid summary of what is known of climate in relation to its influence upon human beings, and then has passed on to a consideration of the effects which it produces upon invalids. The first chapter is devoted to the principles of medical climatology, and after reading this a clear understanding of this important subject can be gained by any intelligent reader, be he medical or otherwise. He then discusses the physiology and ethnology of the subject, and in Chapter IV considers the geographical distribution of disease and then the classification of climates.

In the second section of his book after an introductory chapter he deals with phthisis, the forms of phthisis as influenced by climate, and the results of the treatment of phthisis by climate. Finally, in this section there is a chapter upon the forms of disease other than phthisis which are benefited by climate. The third section of this book deals with the health resorts of North America, Mexico, South America, Europe, Africa, and those of many island climates.

The volume is illustrated by quite a large number of colored plates showing the rainfall in different seasons and different regions of the United States, and by other relief maps showing the geographical arrangement of the surface of the various continents, with particular reference to those spots which are commonly resorted to by invalids. These plates we think add very materially to the value of the volume, as do also the numerous foot-notes and tables which are found on many pages. The practitioner of medicine, in distinction from the doctor of medicine who does not practice and who is interested in matters medical purely from a scientist's standpoint, desires when he picks up a book to obtain information which will directly aid him in benefiting his patients. This book will be found of value to this particular class of medical men, and the author has been so successful in his accumulation of facts that the non-practical class of readers, if such a class exist, will do well to study his pages for the purpose of keeping themselves abreast of climatological learning.

## Correspondence.

### LONDON LETTER.

By RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P.

Following close upon the remarks we made in our last letter on Durham's paper on Peritoneal Sepsis, we have some interesting observations in the April number of the *Practitioner* by Watson Cheyne on the injection of anti-streptococcic serum as a prophylactic in cases of operation involving subsequent sepsis, as for instance in operations on the tongue and throat and rectum. All the three cases related were cases of removal of extensive cancerous growth involving more or less widely the mouth and fauces. It will be remembered that in his recent Lettsomian lectures Watson Cheyne laid great stress on the occurrence of septic pneumonia as the great obstacle to success in such cases, and also referred to the danger of secondary hemorrhage from sloughing after ligature of the external carotid. In the first of the three cases injections of antistreptococcic serum were administered on the two days preceding operation: this was the first case in which no sloughing occurred on the surface of the wound, while there was a complete absence of the common febrile reaction, and no symptom of septic pneumonia. Healing was complete and rapid. In a second similar case, injections of twenty cubic centimeters of the serum were given on the two days prior to operation, and ten cubic centimeters a few hours before the operation. Here again there was a remarkable absence of any septic trouble, and indeed the wound in the skin healed by first intention, while the mouth wound healed rapidly by granulation. In a third case as much as ninety cubic centimeters of serum were injected on the four days previous to the operation, and the progress of the case was in every way favorable, when a fatal issue was determined by the detachment of a thrombus from the lingual artery, which was carried into the brain. In all these cases there was also a remarkable absence of the fetid breath that is so commonly present in these cases as a result of local putrefaction. If this antiseptic value of the serum should prove to be constant, one great obstacle will be removed from the successful performance of these extensive operations on parts where it is impossible at present to keep sepsis at bay.

Professor Bradbury, of Cambridge, reports another case of angina pectoris treated with erythrol tetranitrate. The observations are of especial value as made by the patient, who was himself a medical man. The liability to the anginal attacks had become so constant and severe as to necessitate the constant use of nitroglycerin in anticipation of even the slightest physical or mental exertion. At this juncture erythrol tetranitrate was commenced in one-grain doses, and although the reaction to nitroglycerin had become exceedingly feeble, the effect of the new drug was immediate. Not only was the immediate relief of symptoms more rapid, but the intervals of the attacks were much lengthened; this effect was concurrent with a rapid lowering of arterial tension together with maintenance of this condition for a much longer period than with nitroglycerin. Bradbury asserts that the initial fall depends on the mode of administration: "If the drug is given in spirit and water (one grain in one drachm of alcohol and seven drachms of water) the tension begins to fall in from two to three minutes; if given in a pill and swallowed the time is from twenty to forty minutes; if taken in tablet form and masticated the time lies somewhat between the two. The best form of administration is undoubtedly the tablet form. The alcoholic solution which I originally recommended sometimes irritates the stomach on account of the amount of alcohol it contains, and unless a rapid reaction is required it is better to give the drug in the solid form." Dr. Bradbury claims that the chief usefulness of erythrol tetranitrate lies not in its power of rapidly cutting short an attack, in which it cannot compete with amyl nitrite, but in its affording more prolonged periods of immunity from attacks.

The second volume of Prof. Clifford Allbutt's "System of Medicine by Many Writers" is now issued after a long delay, due to the fact that the article on vaccination could not be written until the publication of the report of the Royal Commission. This volume deals with Infectious Diseases, Intoxications, and Internal Parasites. We are most impressed by the articles of Dr. Sidney Martin on Tuberculosis, of Professor Osler on Malarial Fever, and of Dr. Rolleston on Alcoholism; the former two are specially valuable as records of the individual researches of the authors, while the last is a monument of careful labor in collation. The article by Dr. Dawson Williams on Glandular Fever should also attract general notice, as being the first authoritative account

in English medical literature of a disease that until recently was hardly even recognized. He assigns to it a place in nosology near bubonic plague, to the milder forms of which (pestis minor) it bears some resemblance. He looks to bacteriology to throw some further light on the pathology of the disease. We are also presented with a very substantial article on Vaccinia in Man. Dr. Acland contributes the clinical aspects of the condition, while the pathology is entrusted to Dr. Copeman. Mr. Ernest Hart writes on Vaccination as a Branch of Preventive Medicine; the most useful portion of the article is that on the relations of vaccination and syphilis.

Among other recent books, we gladly welcome two from across the Atlantic, which seem to us likely to find special favor in this country—Holt's "Diseases of Infancy and Childhood" and Hare's "Practical Diagnosis." We have already shown in our acceptance of Professor Osler's "Principles and Practice of Medicine" that we have a hearty welcome in store for the good work of our American brethren.

In a previous letter we drew attention to the appalling amount of venereal disease in the British troops in India, and suggested certain prophylactic measures. We have now the text of the despatch from Lord George Hamilton to the Government of India; it recommends that the rules of the Cantonment Act with regard to cholera, smallpox, diphtheria and typhoid fever should be extended to all venereal diseases. These empower the medical officer of the cantonment hospitals to demand the attendance at the hospital of any suspect, and permit detention for treatment throughout the whole period of communicability. Any disobedience of the suspect to the orders of the medical officer, either in the initial attendance or during the subsequent period of treatment, renders such person liable to expulsion from the cantonment within twenty-four hours; nor is it permissible to return to the cantonment without the written sanction of the medical officer. Thus there is no greater compulsion on women to be examined than applies in the case of other infectious diseases, and any woman objecting to such examination has the alternative course of leaving the cantonment. The Government express themselves as in favor of female medical assistants, under the direction of the medical officer, to examine and treat women. The remaining clauses deal only with restrictions of action, and are obviously thrown in as a sop to fanatics. One clause strikes the

uninitiated lay mind as grotesque to say the least: "Prostitutes must not be allowed to accompany regiments on the march." Has such been the custom in our Indian Army? We were aware that goats, gazelles, and other quadrupeds had functioned as regimental pets, but military lyrics have only told of "The girl I left behind me."

A joint article in *The Lancet* from Drs. Semple and James Taylor deals with an evil to bicyclists which in part has been long familiar to men who ride much and hear much of bicycle lore. This condition consists in a sensation of numbness in the penis and perineum, and in some cases loss of sensation during the passage of urine and feces for some hours after a ride. We have always attributed these effects to direct pressure on the superficial perineal nerves, akin to the bicycle hand, which is sometimes seen in persons who grip their handles too tightly; this affection of the ulnar nerve is analogous to the crutch-palsy of the musculo-spiral nerve. Both the perineal and ulnar affections have been attributed to concussion, but the evidence of this has always appeared to us to be somewhat shadowy. The perineal trouble occurs chiefly in beginners before they have acquired an upright posture in the saddle, and in those who habitually maintain a hunched-up attitude. In many cases immediate relief follows an improvement of posture, but in others it is necessary to have recourse to some form of grooved peak, so as to remove the pressure from the sensitive structures in the mid-line of the perineum; in fact such a peak is desirable in every case, as whatever the posture it is inevitable that as soon as the leg is straightened the greater part of the body-weight should be temporarily thrown on the perineum. The writers of this paper had seen one case of myelitis that had followed on these perineal symptoms, and suggest that the condition was at first one of actual neuritis, which by extension lit up a similar inflammatory condition in the cord. Certainly the march of the symptoms suggests such a sequence, but in the absence of more abundant evidence we suspend judgment.

Professor Charteris vaunts a specific for seasickness; the remedial agent is chlorobrom. From his own considerable personal experience he assures us of its unfailing efficacy to alleviate, and in most cases to cure, *mal de mer*. He suggests the desirability of an initial cholagogue purge followed by the free administration of chlorobrom until relief

is obtained. The drug may be effectively used either as a prophylactic or as a curative agent when seasickness has already set in.

A glance at the report of a committee appointed to inquire into the working of the special hospitals of London is instructive. The report is based on personal inspection of forty-one such institutions, casually selected. The Commissioners report: "That considerable abuse exists among these special hospitals in the following ways: (1) by the treatment either free or for a small sum of patients who could afford to pay a reasonable fee outside; (2) by the admission of patients who do not actually require treatment by a specialist; (3) by the treatment in some instances of more patients in a given time than can be considered either advisable or defensible." On a dispassionate view of these conclusions we cannot realize any very substantial grievance against the special hospitals. One or two subsidiary matters certainly demand immediate redress. Every one will of course be agreed that a hospital for cancer which traffics in cases of abscesses, syphilis, and piles, obtains money from its subscribers under false pretences. It is difficult to imagine any self-respecting body of medical men countenancing such an abuse. Again those patients who can afford a general practitioner's fee and do not require the skill of a specialist should certainly have no claim on a hospital. On the other hand we feel strongly that those cases that require treatment by a specialist, and that cannot afford his private fees, should have as much claim on this special skill as the man in the gutter; and we can conceive no more equitable plan than that which the Commissioners condemn, that they should pay of their means to the institutions from which they seek relief. The real evil seems to us to lie in the excessive number of special hospitals, many of which exist solely for the advancement of interested individuals. The abolition of two-thirds of those now in existence would do much to restore to the teaching schools the valuable clinical material that has gradually been drained away from them, would promote the welfare of the residue of the special hospitals, and sweep away the rank and file of unskilled laborers, who serve merely to bring discredit on the specialty they profess. The general hospitals are themselves chiefly to blame for the multiplicity of these mushroom growths by reason of their slowness to recognize the necessity of specialism, and their failure to adequately equip special departments.

### THE LIMITED USEFULNESS OF QUININE AS A REMEDY FOR UTERINE INERTIA.\*

By H. A. HARE, M.D.,

Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia.

The subject with which this article deals was suggested to me to some extent by a conversation had with my friend, Dr. Barton Cooke Hirst, the Professor of Obstetrics in

A paper read before the Obstetrical Society of Philadelphia, April 6, 1897.

the University of Pennsylvania. He stated that in his experience quinine rarely if ever has acted efficiently in cases of uterine inertia; on the contrary it has often produced not only no effect for good but actually imperiled the life of the patient by producing alarming post-partum hemorrhage, or, if this disastrous symptom has not developed, the full dose of quinine usually recommended for this purpose has resulted in all the disagreeable symptoms of fully developed cinchonism.

Our information regarding the influence of quinine upon the uterus or the nervous spinal centers controlling this organ is unfortunately very meager, and even those persons who have ventured to advance an hypothesis as

to its action have not gone further than that the drug by its general tonic effect, which supports the system under a strain in daily life, comes to the aid of the parturient female who, weak at the beginning of her labor or who has developed uterine inertia in its progress, needs something to renew her energies. That quinine is a moderately active supportant to the general system is not to be denied, but that it has any particular selective affinity for the pregnant uterus is not known.

A number of physicians who have given it in large doses to pregnant females suffering from malarial infection have reported abortion as taking place, but it would seem probable that in nearly all these cases the disease was quite as responsible for the effect as the quinine. It is true that Monteverdi has asserted that quinine is capable of inducing abortion, and many others have done likewise; but the great majority of the cases adduced in support of this view do not bear analysis.

Thus we find in the London *Practitioner* (vol. xvii) a statement by Wathen of two cases in which the use of quinine was followed by expulsion of the fetus, but in both of these the patients were ill with epidemic pleuropneumonia and one of the two expelled a tumor of the "shape of a bun" with a fringe to it. The single instances of Roberts (*Practitioner*, vol. xviii) and of Paterson (*Practitioner*, vol. xix) are both useless as indicating that quinine is positively an ecboic, for Paterson's case took ten grains of quinine to combat what she feared was an ague, and Roberts' case was within ten days of labor and had malarial fever.

Other practitioners who have given very large doses of quinine to women in the later stages of pregnancy have been unable to produce the expulsion of the fetus if the mother was not a malarial patient. Thus Chiara of Milan (*L'Union Médicale*, No. 20, 1873) gave thirty grains of quinine a day for two consecutive days to eight pregnant women in the eighth month without any effect on the uterus. In another woman fifteen grains were given daily for a week, and to another for three days, without effect.

A long and exhaustive paper might be written on this subject, but it does not bear directly on the point at issue, since there is a marked difference between the questions as to whether quinine originates uterine contractions or renews or enforces them when once established by Nature.

Without quoting further cases for and

against the view that quinine is capable of inducing labor, I feel justified in stating that the general opinion seems to be that the drug in medicinal doses cannot originate contractions in healthy women.

Turning then to the question as to its power in parturient females, what evidence have we of its power and are there any records indicating that it does harm if not good? An examination of the literature shows that Brunton classes quinine as one of the chief ecboics, and he says "it is said to produce contractions of the gravid uterus and is to be given with care in pregnancy." So, too, we find that H. C. Wood believes quinine to be a useful uterine stimulant in labor, and Lusk's *Obstetrics* quotes Albert H. Smith as saying: "I do not hesitate to give it in every case, because even where there is no decided inertia at the beginning of labor there may be failure of the powers of the mother from early exhaustion and fatigue, and we get the benefit of the quinine in diminishing this tendency and also in promoting the condensation of the uterine fiber after the delivery of the placenta, thus lessening the dangers of post-partum hemorrhage and the annoyances of after-pains so commonly resulting from a slow condensation of the uterine muscle." Smith recommended fifteen-grain doses of the bisulphate of quinine for this purpose. So, too, Winckel quotes Wood and Kleinwächter as recommending quinine in labor for feeble pains in the early stages.

The following statement in part quoted from Albert H. Smith by Playfair is of interest and is the most forcible plea for the use of quinine for its uterine effect that I have found: "The use of quinine as an oxytocic deserves much more attention than it has generally received. I frequently employ it in lingering labor with marked benefit, and it does not seem to have any of the bad effects of ergot. According to the observations of Dr. Albert H. Smith, in forty-two cases of parturition it presented the following peculiar characteristics:

"It has no power in itself to excite uterine contractions, but simply acts as a general stimulant and promoter of vital energy and functional activity. Dr. R. Doyle, of Trinidad, recently writes to point out that quinine given in malarial fever is constantly observed to produce uterine contractions and abortion.

"In normal labor at full term its administration in a dose of fifteen grains is usually followed in as many minutes by a decided increase in the force and frequency of the

uterine contractions, changing in some instances a tedious, exhausting labor into one of rapid energy, advancing to an early completion.

"It promotes the permanent tonic contraction of the uterus after the expulsion of the placenta, women that had flooded in former labors escaping entirely, there not having been an instance of post-partum hemorrhage in the whole forty-two cases.

"It also diminishes the lochial flow where it had been excessive in former labors, the change being remarked upon by the patients, and consequently lessens the severity of the after-pains.

"Cinchonism is very rarely observed as an effect of large doses in parturient women."

This evidence is, however, chiefly the experience of Smith as already quoted (*Transactions of the College of Physicians of Philadelphia*, 1875, p. 183).

Finally we find King (*Manual of Obstetrics*) saying: "Quinine, though not yet generally used in labor cases to reinforce feeble uterine contractions, has been proved of sufficient efficacy in this respect to warrant the hope that it may form a safe substitute for ergot during the first and second stages of labor in the dose of ten to fifteen grains;" and Davis (*Treatise on Obstetrics*, 1896) says: "Quinine has proved a serviceable drug in maintaining the general strength and good uterine contraction."

Davis, however, gives the drug quite differently from all other authors, namely, in two-grain doses every half-hour till twenty grains are taken.

The literature against the use of quinine in uterine inertia is more meager than that for it. It is plain that the teaching of Albert H. Smith tinctures the favorable opinion of those who commend quinine in every authority we have quoted, and the statement of Dorland (*Manual of Obstetrics*, 1896) that "the old method of stimulating the uterus to more forcible contractions by large doses of quinine not only contributes largely to the nausea, and thus increases the discomfort of the woman, but has failed repeatedly in producing the desired effect" finds its origin probably in the teaching of his chief, Dr. Hirst, whom I have already quoted and who I presume is responsible for the following statement in the *American Text-book of Obstetrics* (1895):

"Owing to the recommendations of Albert H. Smith and of Fordyce Barker quinine has had, and still has, a great reputation as a

stimulant to the uterus in labor. The writer's experience with the drug, however, does not permit him to subscribe to a belief in its efficacy as a uterine stimulant in labor. Quinine has the positive disadvantage, moreover, that it will occasionally in certain susceptible individuals produce a violent post-partum hemorrhage."

In order to gain additional information in regard to these disputed facts I sent out a series of questions to the following gentlemen, who have kindly replied as follows:

Dr. Charles Jewett, Professor of Obstetrics in the Long Island College Hospital; Dr. Henry J. Garrigues, Professor of Obstetrics in the New York Post-Graduate School and Hospital; Dr. Edward Reynolds, Instructor in Obstetrics in Harvard University; Dr. E. P. Davis, Clinical Professor of Obstetrics in the Jefferson Medical College; Dr. Richard C. Norris, Physician to the Preston Retreat, Philadelphia; Dr. Chauncey D. Palmer, Professor of Obstetrics in the Medical College of Ohio; Dr. J. Clifton Edgar, Professor of Obstetrics in the Medical Department of the University of the City of New York; and Dr. Edward L. Duer, formerly Professor of Obstetrics in the Philadelphia Polyclinic.

In answer to Question 1—"Has quinine in your hands seemed an efficient remedy for uterine inertia?"—Dr. Jewett replies: "Only partially so. Its influence is never very pronounced and in a considerable proportion of cases is apparently *nil*. I have assumed that its effect is more general than local, rousing the nervous system."

Dr. Garrigues evidently does not employ the drug.

Dr. Reynolds replies: "No effect whatsoever."

Dr. Davis answers: "Quinine in my experience is one of the most efficient stimulants for uterine inertia."

Dr. Norris says: "No, I no longer use it."

Dr. Palmer has little to say for or against its use, as will be evident from the answer to the last question about to be given.

Dr. Edgar answers: "No, it often fails."

Dr. Duer has used quinine as an oxytocic in large doses for many years. In a large percentage of cases it has been seemingly satisfactory, but quite disappointing in many others: "I should be very glad to find a more reliable substitute for this drug to stimulate uterine contraction in labor; at the same time I cannot but believe that quinine is a true oxytocic, and that it can be depended upon to stimulate contractions after the uterus is

once well dilated. It may be said that it only does this after the patient is worn out and requires a strong nerve stimulant; and this may be true, inasmuch as I have observed no direct effect upon the uterus when given at or before the beginning of labor."

In answer to Question 2—"Have you ever seen any untoward effects from its use in labor?"—Dr. Jewett says: "I do not recall an instance, though I have used the drug in a fairly large number of cases. Possibly its usual unpleasant effects are overshadowed by the pains of labor and are not observed."

Dr. Garrigues does not reply, as he evidently does not use quinine.

Dr. Reynolds says: "None, except discomfort from tinnitus."

Dr. Davis replies: "I have never seen untoward effects from its use."

Dr. Norris replies temporary deafness in two cases.

Dr. Edgar answers "No."

Dr. Duer has never had any ill effects, other than the usual ringing in the ears.

In reply to Question 3—"What dose do you consider the proper one if it is employed?"—Dr. Jewett says: "My dose has been ten grains."

Dr. Reynolds replies: "Have given ten grains in a single dose not repeated, and have not used the drug in labor for ten years."

Dr. Davis: "I give two grains of quinine and one grain of scale pepsin in capsule every hour, or two capsules every two hours, until from ten to twelve grains have been taken. It is best administered with milk, broth, or with milk-punch or egg-nog."

Dr. Norris answers ten or fifteen grains repeated in two hours.

Dr. Edgar answers ten grains in one dose or two grains every half-hour till ten are taken.

Dr. Duer: "I usually give thirty grains in two doses, one hour apart, and have never seen any good effects until after the second dose has had time to be absorbed."

In answer to Question 4—"If you have not employed quinine for uterine inertia in the early stages of labor, what have you used for this purpose?"—Dr. Jewett says: "Keeping bladder and rectum empty; patient on her feet or sitting; rectal injection of glycerin; alternate use of hot and cold compresses over abdomen; faradic current through uterus from side to side, or from upper sacral region to posterior vaginal fornix, avoiding child's head; peeling up membranes from lower uter-

ine segment; passage of bougie between membranes and uterine wall; formerly glycerin injections between uterus and membranes, now abandoned; dilatation by hand or by water-bags. Internal interference, however, it is desirable to avoid if possible, owing to increased risk of infection. In the second stage I have used to some extent the fluid extract of ergot in ten-minim doses. It acts to increase the force and frequency of the pains. The effect lasts for an hour when the dose is repeated. I have observed no bad effects on mother or child when the drug has been given in this manner."

Dr. Garrigues replies: "Antipyrin ten grains every hour; chloral hydrate, fifteen grains every half-hour; hot vaginal douche; let the patient get up and walk about. Intra-uterine bougie (English male urethral bougie) best of all."

Dr. Reynolds: "Patience; in two or three cases of simple inertia ten drops of fluid extract of ergot, repeated five or six times and guarded by a constant watch of the fetal heart and every preparation for immediate forceps. In apparent inertia due to tonic constrictions, chloral or ether; in some cases a manual dilatation of the os."

Dr. Davis says: "Drugs are not indicated for uterine inertia in the first stage of labor. Neither quinine nor any other drug has practical value at this time. In general quinine will not excite labor pains, but after the rupture of the membranes quinine is a most efficient general tonic, increasing the efficiency of the nervous system and thereby furthering labor. In the early stages of labor, if a stimulus to uterine contractions is necessary, artificial dilatation of the neck of the uterus should be employed."

Dr. Norris replies: "When prolonged and nagging pain has exhausted the patient a dose of chloral (ten to fifteen grains) has produced rest, quiet, and sometimes sleep; and in consequence I have seen the pains start afresh and with energy. I have observed good effects from a moderate amount of alcohol (whiskey or sherry) in *private* patients, when exhausted. In many multiparæ a prolonged and tiresome first stage is abruptly terminated and vigorous pains appear when the membranes are ruptured. This, of course, should only be resorted to after the os is well dilated."

Dr. Palmer writes: "I have used quinine very little for uterine inertia. Good results have been reported. I do not think a dose of 10-15 grains would do any special harm.

But I do often make use of it as a uterine tonic, in conjunction with ergotin and strychnine, after labor at term or after abortion, as a prophylactic for the purpose of preventing subinvolution of uterus, as:

℞ Quinine sulphate, 2 scruples;  
Ergotin, 1 scruple;  
Strychnine sulphate, ¼ grain.

M. ft. in pil. xx. S.: One ter die."

Dr. Edgar writes: "In addition to quinine, strychnine (hypodermically), Barnes' hydrostatic bags, digital separation of membranes at internal os, and if necessary *partial* manual dilatation of os. Also hot (110° F.) vaginal douches; stimulating enemata (glycerin and turpentine)."

We find therefore that the general tenor of these replies does not express unbounded faith in the value of quinine as an oxytocic, and it evidently only acts as a stimulant to the general system, as would alcohol or other drug of similar stimulant power.

The next important question to be decided is as to whether quinine does tend in some cases to predispose to post-partum hemorrhage.

There is undeniable evidence that quinine does produce a hemorrhagic effect in some persons, and the records of therapeutics are by no means free from reported cases. The large dose of twenty grains in a strong solution may by nauseating the patient cause muscular relaxation and so produce hemorrhage. The following observations are also useful and interesting. Thus Cachere reports (*New Orleans Journal of Medicine*, October, 1869) the case of a boy of, thirteen years who suffered from hematuria after three ten-grain doses, and in a girl of seven years quinine invariably produced the same result. Ducrot (*Bulletin de Thérapeutique*, xv, 248) has also reported similar effects, and I have called attention to the fact recorded by Karamitsas (*Bulletin Général de Thérapeutique*), Pampouksis and Chomatianos that quinine often produces hematuria in persons with an idiosyncrasy. There seems to be a general consensus of opinion that quinine exercises an irritating influence on the genito-urinary tract, for in support of the views just stated we find that Guyochin (*Action Physiol. et Thérapeutique de la Quinine*, Paris, 1872) reports such cases, and Fagioti does likewise. Monneret and Rivet (*L'Union Médicale*, November 1, 1884), Dasset (*Bulletin de Thérapeutique*, xv, p. 248), reports hematuria with urinary retention. Nor does the evidence as to the hemorrhagic influence of quinine cease at this

point. Gauchet reports hemoptysis, and Simon de Ronchard (*Thérap. de la Quinine*, Paris, 1872) saw several such cases after the use of eight grains a day, the lungs and heart being healthy. A stoppage of the quinine resulted in an arrest of the hemorrhage.

Finally we find the following interesting case reported by Gelineau and quoted by Stillé: A woman in delicate health took ten grains of quinine on an empty stomach and was attacked in about two hours with rigors and cold sweats. The face was pale, the eyes sunken, the pupils dilated, the teeth clenched and the limbs stiff, and a bloody discharge from the vagina came on although menstruation was not at hand.

So far as evidence is concerned pointing to post-partum hemorrhage being produced by quinine, I am unable to adduce any other than that already quoted from Hirst.

It seems evident, however, that quinine is not a first rate uterine stimulant, and that for this reason its ordinary contraindications are so great as to limit its oxytocic usefulness. As pointed out in my "*Text-book of Practical Therapeutics*" these contraindications are as follows: gastritis, cystitis, meningitis, epilepsy, cerebritis, middle-ear disease, and in those cases which have an idiosyncrasy to its action.

#### TURPENTINE AS A REMEDIAL AGENT.\*

BY JAMES B. WALKER, M.D., Ph.D.

Channels of ingestion, digestion, secretion and ejection being possessed of mucous linings, and these, whether for air, food, secretions, or excretions, being so extensively distributed through the body and all communicating directly or indirectly with that disease-laden environment, the external air, it is but little wonder that catarrhal diseases constitute so large a portion of human ailments. While most of these catarrhs disappear entirely soon after the acute symptoms subside under the healing influence of the *vis medicatrix naturæ*, still many remain to harass the patient for an indefinite period as subacute or chronic catarrhs.

The experience of the medical profession with this class of diseases has been very extensive during the past few years, since influenza has become endemic. Methods of treatment of these catarrhs must therefore be of interest to us; and from an extensive

\* Read before the American Climatological Association, Washington, May 6, 1897.

use of turpentine in these conditions I feel justified in presenting for your consideration some of its virtues. I wish, however, at the outset to disavow any inclination to pronounce it either a cure-all or of universal application; or that other agents in other hands may not be as efficient. Its action in subacute and chronic catarrhs seems to be that of a *stimulant alterative*; and as when given by the mouth it reaches, before elimination from the body, every mucous surface in a less or greater degree, its service is not a matter for much surprise.

There is no doubt it is also decidedly anti-septic, but its value in this respect has not been agreed upon by the bacteriologists. The knowledge of the value of turpentine has been so long a part of medical lore, so much has been written by our fathers concerning clinical experience with it, that it would seem an unnecessary task to reiterate the facts concerning it. But truths are established and forgotten in medicine as elsewhere, and most of the written advocacy of this agent is buried in the pile of forgotten, and much of it well forgotten, lore.

The unceasing procession of new remedies, many of which are of great value and most of which claim at least passing attention if not deeper study, crowds from view and from mind those of older fashion and use and relegates them to a limited occupancy in our armamentarium.

On these accounts it is that I have chosen to claim a portion of your valuable time, that I may present some facts, as I believe them to be, no one of which is altogether new and most of which may be familiar to every one present.

The virtues of turpentine to which I desire to call especial attention are those concerning its usefulness in *subacute and chronic catarrhs* and as a *hemostatic*.

Geo. B. Wood established it upon a secure basis in the relief of typhoid ulceration, proving conclusively by its influence on the tongue and the "typhoid condition" generally, the great value of the drug; as well as establishing it as a hemostatic in this class of cases. To use his own expression, "it is one of our best hemostatics." J. Smith of London, in a monograph on Turpentine published in 1856, speaks of it in the same words. Hunter recommended it in hematemesis, and Graves and Seymour confirm its utility in similar cases. Aitken speaks of it as highly recommended by Budd; a Watson Edition, 1872, says "it is recommended as a *specific* in hema-

temesis." Fagge says "some writers have spoken of it very highly." Horatio C. Wood gives it more generous recognition in his *Materia Medica* than most later authors. In speaking of its use in ulceration of the bowel he says "in old gastric ulcer good results are sometimes derived from its use." In the *Practice of Medicine* by Wood and Fitz he says, however, that in acute cases of hematemesis it may not only not do good but may prove absolutely harmful; though not suggesting how this harm is to be brought about. Other modern authors, so far as I have been able to consult them, whether in the elaborate systems of medicine or the less pretentious text-books, are absolutely silent on the virtues of this hemostatic in gastric ulcer, though generous in supporting bismuth, silver, lead, iron, tannic acid and other vaunted hemostatics, no one of which is retainable by an excessively irritable case and any one of which by increase of emesis tends directly to increase the hemorrhage. Referring to these authorities as to the treatment of catarrhal conditions or of hemorrhage from mucous surfaces, the great value of turpentine is almost invariably recognized as to the condition in typhoid fever, whether the object is to allay irritative diarrhea, lessen tenesmus, modify the ulcerative process, or arrest hemorrhage; but in like conditions arising from other causes or in other diseases the potentiality of the drug is forgotten.

One cause, I am sure, of the neglect of so potent a remedy has been the large doses (half-ounce) in which it was formerly given and the distasteful emulsion which some would-be pharmacist foisted upon a gullible profession.

My first acquaintance with turpentine, barring some very juvenile personal experience with its administration on a teaspoonful of sugar for vermifugal purposes, was while a student of medicine. The case was one of ulcer of the stomach, occurring in a previously healthy young lady, who was rapidly rendered almost exsanguine by the most excessive hemorrhages I have ever known. The ordinary remedies had not only failed to relieve, but each in its turn seemed only to aggravate the hematemesis, until the case seemed absolutely hopeless. At the suggestion of a lay woman who had known of a severe case of vomiting of blood which was arrested by turpentine, it was resorted to by Dr. Pawling of Montgomery county, Pa., who had charge of the case. The first dose was the first thing retained for days, and there-

after cure was rapidly effected, without resort to other aid save the ice-bag, which had been in use from the first. Watching this case throughout and noting the almost marvelous action of this remedy after other so-called hemostatics had each but aggravated the hemorrhage, until we feared to use any internal agent lest fatal hemorrhage might occur, established to my satisfaction at least the value of turpentine as a hemostatic; and I have since used it in a number of cases of gastric ulcer in hospital and private practise and have had my first impressions firmly established.

Its benign influence in irritable cases is inconceivable without personal experience, though I am satisfied a great deal depends on the method of administration. The best method in gastric cases with decided irritability is in suspension. The globule or capsule forming a palpable mass will often be rapidly ejected, whereas the diffusing vapors from the solution rapidly dispersing through the viscus may be retained. The best solution is, not the gummy emulsion, unpalatable and nauseous to most and which I think is to be named only to be condemned, but the solution made at the bedside, dose by dose, by stirring two to ten drops of oil of turpentine in an ounce or two of water well sweetened with the *Saccharum Anisi* of the German Pharmacopœia. The acrimony of the turpentine is by this means entirely corrected, if the proper amount of the medicated sugar is used; and both palate and stomach accept it readily if not eagerly. This is the preferable method in administering it to young children, for whatever purpose it is given, and for all cases at whatever period of life if an irritable stomach is to receive it.

Where an angry viscus or the age of the patient is not a consideration the sealed capsule, soft or hard, is to be preferred. It might be added that this or any other volatile agent should never be administered in the bivalve capsule, so convenient for non-volatile substances.

In hematemesis from other causes than ulceration it may serve as a valuable hemostatic. In that arising from chronic alcoholism or in chronic venous engorgement from other causes it is more efficient than the astringents, and combined with hygienic necessities will often prove efficacious. If hepatic obstruction exists it of course can only effect its hemostatic purpose.

As an illustration of its gentle efficiency I will recite a case of its use in an infant. In

August, 1896, Elizabeth F., aged three days, was noticed to be extremely pale, and on inquiry I learned she had been vomiting blood at intervals for two days, and her stools were tarry. Finding no cardiac cause for the same, I gave oil of turpentine as a hemostatic and there was no further hemorrhage and the child thrived uninterruptedly until it was four months old, when the hemorrhage was repeated and with equally effective use of the turpentine. I am sorry to admit that in neither case was I able to find the cause of the hemorrhage.

But it is not alone in ulceration with or without hemorrhage that turpentine proves itself a boon in gastro-intestinal troubles. In subacute and chronic catarrhal conditions it is of equal value. Its property of rapid diffusion distributes it throughout more or less of the entire intestinal tract, and brings it into intimate contact with the catarrhal area more rapidly and more certainly than any non-volatile remedy, and applies whatever healing virtue it may possess more surely wherever it is required. In the past six years the proportion of catarrhal diseases has greatly increased, and in many cases the gastro-intestinal tract especially suffers. Whether these cases are really cases of la grippe or merely seasonal or climatic catarrhal troubles I leave to others to discuss; but we must all admit, especially those living along the Atlantic seaboard, that these catarrhs accompany other manifestations of la grippe, both as to time and place, and the terms la grippe of stomach or bowels may not be so markedly inaccurate as some claim. Even appendicitis, no longer attributed to wandering fruit seeds, but recognized as often at least of catarrhal origin, has by its great multiplication in the same grippe period emboldened me to believe that it *owes its origin in the great majority of cases to the same catarrhal cause.*

In these catarrhs of the stomach and intestines, after the acute symptoms subside, there is often left an irritability which lingers to annoy, and when in the stomach to even threaten life. The tongue in many of these cases has not the usual appearances suggesting turpentine, which have become classical. Often it is pale and but slightly furred, with a whitish or yellowish white coat. And yet the stomach may reject all ingesta, even water; or it may be less irritable, with dyspeptic symptoms, and annoying chiefly because so persistent. In the bowels the pain is usually referred to the suprapubic and in-

guinal regions, accompanied by a sense of heaviness and a general feeling of languor and depression. For these conditions no remedy has served me so friendly a turn as the oil of turpentine. Of course the hygienic indications have been followed also, and I would not have it understood for a moment that I advocate this or any other remedy to the avoidance or neglect of dietetic and other hygienic attentions. But of the remedies for such a condition turpentine outranks them all. Here it must be administered as before suggested, and where the stomach is non-retentive the solution in anise sugar water, small doses every two hours, is to be resorted to. In the other cases the five-minim capsule should be given an hour after meals, when it will be least likely to be regurgitated; an extra capsule may be given at bedtime if there is much tympany or irritation.

I could give numbers of illustrative cases to support what I have asserted, but perhaps all are as familiar with this use of the drug as I am myself. The look of surprise on more than one physician's face when I have suggested this remedy for such a condition, however, causes me to believe that its value in such cases is not universally appreciated. And I may add that the enthusiasm with which these same physicians after using it speak of it establishes me the more firmly in my estimation of its value.

In catarrhs of the respiratory system after the acute symptoms have subsided, where a free secretion is present or where the catarrh persists, with or without localized subcrepitant râles, so frequent in lingering attacks of influenza, its value is exceptional. Being excreted in part by the pulmonary mucous membrane it reaches directly from within the surfaces and even the cells of the tissues involved. It is greatly preferable to the ammonia salts, because more efficient and more acceptable to palate and stomach. In the more chronic cases, where creosote and guaiacol are recommended, it has been in my hands equally efficacious and often less objectionable.

In the bronchial catarrhs of the aged and the infirm of any age its stimulating qualities as well as its local alterative effect make it invaluable.

In the catarrhal conditions of phthisis, especially when bronchorrhea is present and even where the secretion is only fairly free, its remedial effects are easily appreciated; and here again, whether cavities are present or not it should rank equal if not superior to

creosote and guaiacol. In the hemorrhages of phthisis, as I have already stated before this Association, it should hold first rank among drugs. Here as in intestinal catarrhs and hemorrhages its internal administration may be supplemented by its external use in form of a stupe, although in some, perhaps most, instances the ice-bag is preferable for external application.

Inasmuch as the renal shares with the pulmonary mucosa in its elimination, it finds opportunity for service in chronic catarrhs of the urinary tract. I have not used it in chronic catarrhal nephritis, but believe that cautiously used in small doses in cases under close and frequent observation it will often serve us a good turn, in the almost hopeless maiming to which the renal mucosa is subjected in this form of Bright's disease. Certainly in chronic vesical catarrh, with or without enlarged prostate, it has proven of much value in a few cases where it has been given. In chronic cystitis and urethritis of gonorrheal origin it is of extensive usefulness, its action being similar to, though I believe more certain than, the oil of sandalwood so generally employed.

In hematuria it has the same virtue as a hemostatic as in other mucous hemorrhages.

I could recite a number of instances where in metrorrhagia without tumor or other palpable cause turpentine has served me a good turn.

Of its action as a diffusible stimulant affecting the system generally and especially the heart, and through the improved circulation the entire economy, I will not dwell at this time.

1617 GREEN ST., PHILADELPHIA.

#### THE TREATMENT OF COMPLICATED ULCERS OF THE CORNEA.\*

BY CLARENCE A. VEASEY, A.M., M.D.,

Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic; Demonstrator of Ophthalmology, Jefferson Medical College; Chief Clinical Assistant to the Ophthalmological Department, Jefferson Medical College Hospital; Consulting Ophthalmologist, Philadelphia Lying-in Charity, etc.

In a former paper† it was suggested that for all practical purposes corneal ulcers be divided into two great classes, the simple

\* Read before the forty-seventh annual meeting of the Medical Society of the State of Pennsylvania.

† The Treatment of Simple Ulcers of the Cornea. The Philadelphia Polyclinic, June 22, 1895.

and the complicated. By a simple ulcer is meant one that makes its appearance as a small, superficial, grayish lesion of the cornea, with no marked tendency to spread and with slight inflammatory symptoms such as injection of the conjunctiva, moderate lachrymation, and perhaps more or less intolerance of light. By a complicated ulcer is meant one that is more or less extensive, that shows a disposition to spread rapidly and involve other portions of the cornea than that first affected, and which produces all of the symptoms found in connection with a simple ulcer in a markedly exaggerated form. In the paper above referred to the author discussed the treatment of the first class, or simple corneal ulcers. In the short time at his disposal to-day he will endeavor to discuss briefly those methods of treatment of the second class, or complicated corneal ulcers, that have proved to be the most satisfactory in his own work.

A corneal ulcer ordinarily presents itself as a small grayish spot, the surrounding portion of the cornea being more or less hazy. This haziness may be a solid infiltration in all directions around the ulcer, or the latter may be a central point from which numerous striæ pass in various directions. The eyeball is more or less injected, there is excessive lachrymation, intolerance of light, and pain, the latter sometimes being out of proportion to the severity of the lesion owing to the distribution of nerves in the anterior layers of the cornea.

In the treatment of complicated corneal ulcers we begin as in the simple cases, by searching for the cause and removing it if possible. We look for foreign bodies either in the ulcer itself or upon the under surface of the lids where they may have lodged, and by constant scraping of the cornea as the lids were opened and closed have caused a denudation of the corneal epithelium, resulting in ulceration. In the same way misplaced cilia and small growths frequently cause corneal ulceration. But by far the most frequent cause, especially in children, is intranasal disease extending upward through the lacrimal ducts into the conjunctiva and thence to the cornea; and in all cases in which this condition is found the treatment must be directed towards it as well as towards the ulcer itself.

In the local treatment it is better to begin with the employment of those remedies found to be of the greatest service in the treatment of simple corneal ulcers, as many of the more

complicated cases yield to these alone. They are as follows:

1. *Moist Heat*.—In applying moist heat to the eye the object is to keep up a continuous uniform high temperature for some time at regular intervals, and this is done in the following manner: Several small pieces of lint or flannel about three inches in diameter are dipped into water as hot as the hand can be held in for an instant, or at the temperature of 120° F., and laid on the closed eyelids, three or four thicknesses being employed, as the heat is better retained in this way. In from one to one and one-half minutes these are replaced by others, more hot water being repeatedly added to keep up the temperature. Heat applied in this manner should be employed for fifteen to thirty, or even sixty, minutes at a time, and should be used from three to eight times a day according to the virulence of the ulcer.

2. *Cleansing Solutions*.—Immediately after using the moist heat, and between the applications if there be much discharge, the conjunctival cul-de-sac and the cornea should be thoroughly cleansed by means of some soothing lotion. For this purpose a saturated solution of boracic acid, or a solution of mercuric chloride (1:6000), answers the purpose very well, though solutions of other remedies may be preferred by others, as chlorine water, cyanuret of mercury, permanganate of potash, or formaldehyde. The latter drug in the strength of 1 part to 4000 has proved of the greatest service in those varieties of corneal ulcers having a tendency to spread with unusual rapidity and complicated with hypopyon, but must be employed at frequent intervals, namely, every hour or two. Whatever solution is employed should be warm, and this temperature is readily secured by standing the bottle containing the solution in a basin of hot water for a few moments before using, care being taken to test the solution on the back of the hand before placing in contact with the eye.

3. *Instillation of Atropine or Eserin*.—A drop of a solution of the sulphate of atropine (four grains to the fluidounce) is dropped on the cornea two or three times a day, provided the ulcer be situated near its center. This combats any impending inflammation of the iris and reduces the general irritation of the eye, in this manner acting favorably upon the ulcer itself. But should the ulcer be situated near the margin of the cornea a drop of a solution of the sulphate of eserine

(one-sixth or one-fourth of a grain to the fluidounce) may be employed instead. The latter promotes healing by stopping the migration of the white blood-corpuscles, by promoting absorption through dilatation of the ciliary vessels, and by reducing intra-ocular tension if this be elevated. It should be employed from three to six times a day, and as it possesses a tendency to cause congestion of the iris and ciliary body it is better during the time of its employment to counteract this tendency by instilling at night a drop of the solution of atropine. Should there be at any time any complication involving the iris or ciliary body the eserine must be discontinued and the atropine employed in its place.

4. *Protection*.—The eye should be protected by dark glasses or a bandage. If much discharge is present it is evidently improper to dam it up in an already inflamed eye; in such a case dark glasses being preferable. If the amount of the discharge be small a well-applied bandage will materially assist in the reparative process, it being left off long enough for the application of the other remedies. It should be applied lightly but firmly, and should keep the lids closed and at rest without making any pressure on the eyeball, unless this should be required. It also keeps out such extraneous matter as dust, and should be worn until the floor of the ulcer is covered with epithelium, which protects it from external irritation.

Should the ulcer seem disposed to spread rapidly, to become more virulent in action, and to involve greater destruction of the corneal tissue in spite of the faithful employment of the above-mentioned remedies, our measures for checking its progress and producing resolution must necessarily be somewhat more severe. In the order in which they are employed they are as follows:

5. *Curettement*.—The ulcer may be curetted by an instrument specially devised for this purpose, or if this is not at hand it may be done more or less perfectly with a sterilized probe on the end of which has been wrapped a wisp of aseptic absorbent cotton. The cornea is first anesthetized with a solution of cocaine, or eucaine, after which a drop of a two-per-cent. solution of fluorescein is instilled and the excess washed off, this substance having the power of coloring the ulcerated portion light green, while the remaining portion of the cornea having its epithelium intact remains unchanged. The use of this preparation,

therefore, is of decided advantage, as it maps out for the operator the exact portion to be curetted and enables him to avoid injuring the healthy parts of the cornea. The sides and back of the ulcer are relieved of the slough as far as possible, and after a drop of the atropine solution is instilled some finely powdered sterilized iodoform is dusted upon the cornea, and a light pressure bandage applied. This is repeated if necessary on the succeeding day. Recently the author has also obtained some excellent results from the use of finely powdered acetanilid employed in place of the iodoform.

Hydraulic curetting as a method of treatment has recently been suggested, and it is carried out by having a receptacle containing the antiseptic solution to be employed held on a higher level than the eyes, while a nozzle with a fine point, connected with the former by means of a rubber tube, directs the stream for some minutes against the ulcer.

6. *Topical Application of Chemicals*.—If after a fair trial of the curette, the iodoform and the bandage, together with the use of moist heat, atropine, or eserine, according to the indications already stated, the ulcer should continue to grow worse, it is best to attempt to bring about a healthy condition by the application of some one of the chemical agents used for this purpose. The ulcer is first curetted in the manner described and the chemical agent is brought in contact with every portion of it by means of a wisp of cotton wrapped on a pointed probe, or stick, previously sterilized. For this purpose one of the simplest as well as one of the best stimulants is the tincture of iodine. Stronger agents, actually cauterizing the parts, are solutions of silver nitrate (ten to thirty grains to the fluidounce), liquid carbolic acid, and strong solutions of bichloride of mercury (1:500). In applying these care must be taken to touch only the affected parts, as an application to the healthy cornea would result in an opacity of greater or lesser density; and as an opacity always results from corneal ulceration, except the most superficial, it must be our object to keep it as small as possible. After the application of the chemical agent the eye is treated as after curettement.

7. *The Actual Cautery*.—Among the more severe remedies at our disposal, when those previously referred to fail to check the progress of the ulcer, is the actual cautery, and in very few cases does the proper use of it fail to prevent the further extension of the disease. In the execution of this method of

treatment we may employ the elaborate cautery outfits of the shops, if they are at hand, but a simple as well as most effective cautery probe can be had by inserting a piece of medium-sized platinum wire into the so-called "universal" laryngoscope handle. An assistant holding an alcohol lamp near the head, all draughts being avoided so that the flame will be steady, the end of the probe is brought to a white heat and quickly transferred to the ulcerated portion of the cornea, this having been mapped out by the use of fluorescein after the cocaineization of the eye and the eyeball being firmly held with the fixation forceps. As before stated the sides and base of the ulcer must be thoroughly cauterized, but care must be taken to avoid injury to the healthy tissue. Properly applied the actual cautery leaves a scar no larger than, if as large as, would have been the case if it had not been used; but improperly applied it increases the size of the corneal scar and therefore decreases in proportion the visual acuity. The eye is dressed as after the application of the chemical agents.

If at any time during the treatment of the disease the cornea threatens to perforate, as indicated by a slight bulging of the base of the ulcer, a bandage is evenly applied, making gentle but firm pressure; and if in spite of this the bulging continues to increase it is better to anticipate perforation by performing paracentesis of the anterior chamber through the floor of the ulcer itself if the conditions are favorable.

8. *Intranasal Treatment.*—In those cases having considerable discharge of mucus or muco-pus from the nares it is well to cleanse the parts several times a day with a mildly alkaline solution, such as Dobell's, one-fourth strength, and to follow with the insufflation of some of the following powder:

- ℞ Pulverized camphor, 30 grains;
- Pulverized aristol, 10 grains;
- Pulverized menthol, 20 grains;
- Bismuth subcarbonate, 2 drachms.

Mix.

If the mucous membrane on the turbinated bones be much swollen it may be sprayed with a solution of antipyrin (ten to thirty grains to the fluidounce), the parts then cleansed with the alkaline solution, and this followed by the spray of an oily preparation:

- ℞ Pulverized camphor, 30 grains;
- Pulverized menthol, 30 grains;
- Liquid petrolatum, 1 fluidounce.

Mix.

The topical application of the compound

tincture of benzoin has also been found of much benefit in these cases.

If there is any gross lesion such as a polyp, a spur, or septal deviation, it must be attended to as early as possible, and this also applies to any disease of the lacrimal duct.

9. *Constitutional Treatment.*—As with disease manifesting itself in any other part of the body the constitution must be put in the best possible condition. Instead of confining patients to a darkened room, as a rule it will be better to allow them to pass several hours a day in the open air, the eyes being properly protected. Any particular diathesis that is present must be especially attended to, and in large, progressive ulcers the system must be supported by stimulants, and quinine administered. In the beginning it is advisable to give a brisk purgative followed by a saline draught. The diet must be digestible and nourishing, all sweets being interdicted. If pain is severe and continuous and not relieved by the means suggested above, the antineuralgics or even opiates are indicated.

In the preceding remarks those methods of treatment that have been of the greatest use to the author in the management of such cases are given in the order in which they are usually employed. It is impossible in the brief time allotted to this paper to discuss the many complications that may arise during the treatment of a given case. No fixed rules can be made, but a general plan has been outlined, to be modified as emergencies demand.

Many other methods of treatment have been advocated by various surgeons, but brief mention will be made of only one, viz., the subconjunctival injections of solutions of mercuric chloride. As stated elsewhere, personal experience in the employment of these injections for the treatment of ulcerative disease of the cornea has not given to them the position of value to which they have been assigned by many ophthalmic surgeons. Experience in the treatment of a large number of cases during the past three years has shown that injections of a solution of sodium chloride beneath the conjunctiva prove equally as beneficial as injections of a solution of mercuric chloride, and that neither of them is of much value in the treatment of this class of cases.

To recapitulate, the treatment of complicated ulcers of the cornea should be carried out in the following order:

1. Examine thoroughly the conjunctiva, the lacrimal ducts, the nares and naso-pharynx, as well as the cornea itself, and if any

abnormal condition be found that is either the primary cause of the ulcer or that is keeping up the condition, direct the treatment against it as well as against the ulcer itself.

2. Employ moist heat by means of the local application of pieces of lint or flannel wrung out in hot water at a temperature of 120° F. from fifteen to sixty minutes at a time, repeating at intervals varying from two to four hours, according to the virulence of the disease.

3. Cleanse the ulcer and the conjunctival cul-de-sac with some warm antiseptic solution immediately after the employment of the moist heat, and between the times of its employment if there be much discharge. For this purpose may be used a saturated solution of boracic acid, a solution of bichloride of mercury (1:6000), or a solution of formaldehyde (1:4000).

4. Instil a drop or two of a solution of atropine (four grains to the fluidounce) once or twice daily if the ulcer be central; but if it be peripheral, a solution of eserine (one-sixth of a grain to the fluidounce) may be employed from three to six times during the day, and the atropine solution instilled once at night.

5. The eye must be protected by dark glasses or an evenly and lightly applied bandage. As a rule the former should be used in those cases in which there is considerable discharge, the latter in the cases in which very little discharge is present.

6. Should the above means fail to check the progress of the ulcer it should be curetted, and after dusting on its surface some iodoform, previously pulverized and sterilized, a bandage should be applied.

7. Should the ulcer continue to spread, after being curetted it should be touched with some one of the chemical agents employed for the purpose. Of these the tincture of iodine, liquid carbolic acid, and silver nitrate (the latter in the strength of ten to twenty grains to the fluidounce) seem to be the best.

8. The actual cautery should be applied after the previously described remedies have been employed without beneficial result, or even before these have been used if it be seen that the ulcer has assumed a malignant type—that is, if the cornea is becoming so rapidly involved that the destruction of all, or a large portion, of its tissue is threatened.

9. Any unhygienic condition, dietetic error, or constitutional diathesis should be corrected.

## TREATMENT OF ACUTE ANTERIOR URETHRITIS IN THE MALE.\*

BY JOHN LINDSAY, M.D.,  
Instructor in Genito-Urinary Diseases at the Philadelphia Polyclinic, and First Assistant Demonstrator of Anatomy at the Jefferson Medical College.

The treatment of gonorrhea, or clap as it is somewhat affectionately called by the laity, interests every practitioner of medicine for several reasons: first, it is the most common of the three great groups of venereal diseases and is always present in the community; second, it is no respecter of persons, since the man of leisure and the artisan here meet on a common if not sacred ground; and lastly, the views held by the profession, as also unfortunately by the public, are so different and numerous that one is often puzzled to know exactly what are the guiding principles that should govern the treatment of urethritis.

Before considering the question of treatment it is necessary to take into account, briefly, the nature and functions of the urethra. The teacher of anatomy describes the urethra as being divisible into three portions—a prostatic, membranous, and spongy—and no better subdivision is to be desired for descriptive purposes; but the division of the genito-urinary surgeon is different, depending upon the part played by the compressor urethræ or cut-off muscle, and consequently he only speaks of an anterior and a posterior urethra, his anterior including everything in front of the anterior layer of the triangular ligament, the posterior embracing what is left. This division of the urethra gives to the clinician an exact and useful nomenclature, since he can and does speak of anterior urethritis, or urethritis, and posterior urethritis, the latter being viewed by many as a complication, equally with epididymitis, prostatitis, or cystitis, that is placed precisely in the same category as other parts in direct anatomical relation by continuity of structure with the anterior urethra. Though usually represented in diagrams as a hollow cylinder, let the urethra be viewed as a collapsed tubular valve between the bladder and the outer world, about seven to eight inches long, having a double purpose: first, as a root for the escape of urine; second, as a spermatic conduit, thus making the urethra necessarily as long as the penis. Now, this urethral gain in length is the penalty paid by the male for his

\* Paper read before the Philadelphia Chapter of the Jefferson Medical College Alumni Association on May 10, 1897.

sex, as Sir Henry Thompson has so aptly and instructively observed. When it is seen that the urethra is composed of a mucous membrane, perhaps the most sensitive mucous surface in the body, a submucous connective tissue layer, and a muscular coat, that it is surrounded by erectile tissue, particularly the penile urethra, that its caliber is a varying one, that its mucous membrane has many follicular depressions or glands, and that by continuity of structure its anatomical relations extend as far as the kidney, and finally when it is acknowledged that "the temper of the urethra varies as much as the temper of the mind," it causes the realization that even anterior urethritis is a disease of importance and should be treated with a reasonable amount of thoroughness and care.

Having considered the site awaiting the disease gonorrhea, it is desirable and necessary that a cause be assigned, if possible, in order that our line of treatment may be a rational and consequently hopeful one. I believe the majority of cases the practitioner has to meet depend for their development upon the presence of the gonococcus of Neisser, discovered in 1879, and those cases in which the above germ cannot be found are to be attributed to some other pus-producing micro-organism—in other words, I am a supporter of the view that the origin of gonorrhea is a microbic one. This explanation of the etiology of urethritis is of great practical value in formulating a plan of treatment.

Anterior urethritis presents, clinically, three stages, viz: a first or increasing stage, lasting about one week, with ardor urinæ and purulent discharge as constant symptoms, and usually, though not always, chordee and frequent urination; a second or stationary, lasting about two weeks, with continuance of the above symptoms; and a third or subsiding, in which all symptoms in uncomplicated cases tend to disappear, the duration of this stage being in favorable cases from three to four weeks, and sometimes even longer. This affection being a local disease and not constitutional (a fact that should invariably be impressed upon patients, so that in future there may be no confusion, when it may become necessary for them to give their venereal history to some medical man), and occurring as a rule in men when the sexual wave is at its height, between the years of twenty and thirty-five—that is, when they enjoy a good measure of health—our treatment can usually be directed to the cure of the

gonorrhea *per se*, and the patient apart from his disease discounted therapeutically. Believing in the microbic origin of urethritis—in a typical case—any treatment instituted, to be in line with modern progress, should and must be an antiseptic one. This may be applied to the urethra either directly, by injection, irrigation, instillations, etc., or indirectly, through such drugs as are eliminated in the urine, and are therefore brought into contact with the diseased mucous membrane during each act of urination. In the beginning the surgeon meets with a difficulty, and that is he cannot apply or follow out an antiseptic line of treatment of sufficient thoroughness to disinfect the infected urethra, such as could and would be employed in other regions of the body, this difficulty being due to the excessively acute degree of sensibility of the urethral mucous membrane.

I shall only allude to the abortive treatment, and say that so far as I am aware it is not looked upon with the same enthusiasm as formerly. It would be a very pleasing thing to the professional man to be able to abort an attack of clap, knowing as he does how dangerous and troublesome any attack may become; but so little success has attended the efforts of even the most experienced men in this direction, and since the treatment adopted very often renders the case one of high inflammatory grade, the practitioner may usually avoid the procedures advised in making the attempt to annihilate the malady in its birth. The only methods I shall speak of are injections of strong nitrate of silver solutions, as detailed in all text-books, and Dr. J. Chalmers DaCosta's novel and brilliant plan, where he employs hydrogen peroxide, oil of cinnamon, and benzoinol, the details of which can be found in his paper in the *Medical News*, October 21, 1893. But as few men consult their medical adviser until either method would be too late, the old law again holds good, viz., "that he who breaks Nature's laws will in turn be broken by them."

The following methodic plan of treatment is one frequently employed in the service of Dr. T. R. Neilson, at the Philadelphia Polyclinic Hospital, and it has always been a most successful one, especially in having a remarkable absence of complications during its use, and it effects a cure with as great rapidity and certainty as other methods seem to claim.

In every case certain general directions must be given the patient on his first visit, as the abstinence from all kinds of alcoholic

stimulants, the avoidance of everything tending to excite him sexually, and instructions as regards diet. While the diet should be of the simplest kind, it should also at the same time be a nutritious one, as for example, milk, eggs, fish, meats, etc., but strawberries, asparagus, cheese, strong tea or coffee, and highly seasoned dishes are not to be allowed. Anything having a tendency to cause too active a circulation should be interdicted, as excesses in walking, bicycling, or horseback riding; in other words, a condition of rest and repose is the rôle the wanderer should now assume. Concerning smoking, I believe when used in moderation no harm results. At this time it is often desirable to inquire into the state of the alimentary tract, which if not in good order should be put right, as perhaps in the ordering of a mercurial pill, to be followed by a saline; and above all one should never neglect to warn a patient about his eyes in treating a first attack of gonorrhea.

One of the early symptoms the sufferer demands relief from is the ardor urinæ, or scalding when passing urine. In this condition the blandest fluids are scarcely tolerated—distilled water—and it therefore follows, as desirable practise, the modifying or neutralizing the acidity of the urine, and also the increasing its dilution. Diluents are useful in two ways: first, by lessening the percentage of salts in urine; and second, by causing the urethra to be washed out frequently. So many people are sufferers from lithiasis that alkaline lithia waters are often here indicated. A well known wrinkle for ardor urinæ is often very effective in affording relief, and that is having the patient void his urine in a tin cup of hot water—in other words, “pass his water under water.”

An alkaline sedative mixture is also prescribed during this early stage, which modifies the ardor urinæ and diminishes the tendency to frequent micturition and chordee. The following combination is one often employed in the service, and it has been found most effective clinically:

℞ Potassii acetatis, ʒij;  
Potassii bromidi, ʒiss;  
Acidi borici, ʒij, ʒij;  
Tincturæ belladonnæ, ℥xxx;  
Liquor potassii citratis, q. s. ad ʒviii.

M. Sig.: A tablespoonful in water three or four times a day.

In giving your directions to the patient it is of importance he understands that a liberal quantity of water should be taken with his medicine, and I think the remedy is better taken about two hours after meals. The

potash salts are to be presented in such doses as the physician believes best meet the individual case. The boric acid is the antiseptic present, and I have never seen it produce any depression in the above dose of ten grains, while the dash of belladonna has its own selective and soothing action on the mucous membrane. This alkaline plan of treatment should not be pushed so far as to make the urine markedly alkaline, because that would bring about ardor urinæ, just as will a too acid urine. The object to be sought is a bland urine. Perhaps the non-observance of this point is the reason why this plan of medication is not in vogue with many of our best physicians so much as formerly. The above combination is continued until the acute symptoms are in a measure relieved, when recognizing the undisputed controlling influence of the balsamics or anti-blennorrhagics, one, or a combination of them, is chosen and exhibited to the patient, as for example, balsam copaiba and oleoresin of cubebs, say seven and a half minims of each in capsule, one or two to be taken four times a day, depending on the severity of the case. This answers the purpose admirably without causing gastric disturbance, this latter being, however, not so frequent an occurrence, judging by our experience in the service, as one is led to believe from the statements generally met with in the text-books. There can be little doubt that this class of medicinal agents has a local action upon the diseased mucous membrane.

Concerning local medication it is of course simply a question how best to disinfect the urethral mucous surface, and as the products of the existing infection are sources of new infection we are more anxious to disinfect as thoroughly as we may with safety.

Nitrate of silver in weak solution, one to three thousand—nitrate of silver one grain, distilled water six fluidounces—used locally three or four times a day, is an admirable agent to avail one's self of for this purpose; that is to say, it is employed for its antiseptic properties and with no idea of aborting the disease. This should be ordered as an injection from the beginning, providing the symptoms do not point to a too irritative condition. When ordering an injection it is always advisable to see that the patient gets a proper cone-pointed and easily working syringe, of a capacity not greater than three drachms, at the same time teaching him the art of giving himself injections. Nitrate of silver is one of the best agents we have for the confining of

the attack to the anterior urethra, and thereby insuring an absence of complications. The use of nitrate of silver gradually lessens the discharge in amount and purulency by the time the stationary stage is well established, from which time on it becomes thinner, looking milky in character. Sometimes in obstinate cases a solution of one to fifteen hundred is employed, with beneficial results.

Astringents are now desirable, as after inflammation of any mucous membrane there is a condition of relaxation with excessive secretion consequent upon the vascular engorgement, which remains behind the acute inflammation. Particularly does this hold good in this highly vascular part. The favorite astringent used in the service has been zinc sulphate (two or three grains to the ounce) in combination with boric acid (ten grains to the ounce)—these alone, or having added a fractional amount of mercuric chloride (one-tenth of a grain in six ounces). Sometimes Ricord's formula is selected, where the zinc sulphate is decomposed by lead acetate, or occasionally tannic acid and zinc acetate (each five grains to the ounce) are prescribed, yielding an extemporaneous tannate of zinc, a most serviceable injection in many cases.

After such a course of treatment the majority of cases can be dismissed as cured, since the discharge will have entirely ceased, this cessation being readily determined by Thompson's two-glass urine test, and careful microscopic examinations.

In those cases in which the discharge still continues we must then seek for the cause, and here an endoscopic examination is of great value to one who has examined a sufficient number of cases to become trained in its use, as it readily shows circumscribed areas of inflammation, etc., and the necessary local treatment can be instituted, as tannic acid, nitrate of silver, or copper sulphate, according to the predilection of the surgeon. Again, the occasional passing of a sound gently is often the one thing necessary to finish the case; not that we are going to cure a stricture, for none can yet exist, but for the effect of pressure and the maintenance of caliber.

I have drawn attention to this nitrate of silver treatment, not because other methods—as for example irrigation with potassium permanganate solutions when practicable—have not a distinct place and value, but on account of its efficiency as demonstrated clinically, especially in the prevention of complications; and finally Neisser himself, after much investigation, advocated it.

## THE TREATMENT OF GONORRHEA BY INJECTIONS OF ARGONIN.

BY H. M. CHRISTIAN, M.D.,

Chief of Genito-Urinary Dispensary, University of Pennsylvania; Adjunct Professor Genito-Urinary Diseases, Philadelphia Polyclinic.

To attain success in the treatment of gonorrhea two conditions should be recognized as present in every case: first, the presence in the urethra of the gonococcus, the exciting cause of the disease; second, the catarrhal inflammation of the mucous membrane of the urethra, resulting from destructive action of the gonococcus upon the epithelium.

The method of treatment usually employed at the present day is to first attack the gonococcus with antiseptic irrigations or injections of either bichloride of mercury, permanganate of potash, or nitrate of silver. For the treatment of the second condition astringents such as sulphate of zinc, acetate of lead, or alum are old and time-honored remedies, and on the whole give as a rule very excellent results. The ideal single remedy for the treatment of gonorrhea should be of course one that would meet both of these conditions—*i.e.*, destroy the gonococcus and at the same time cure the catarrhal inflammation of the urethral mucous membrane produced by the presence of the micro-organism in the urethra. Such a drug up to the present time has never been found.

It will be recalled how, upon the discovery of the gonococcus by Neisser some years ago, that bichloride of mercury was the one drug turned to by all physicians as the most rapid and efficient cure for gonorrhea.

The subsequent results following this popular method of treatment are now a matter of history. Solutions strong enough to kill the micro-organism were violently irritating to the mucous membrane of the urethra, increasing epithelial exfoliation and thereby favoring the culture of the gonococcus. On the other hand solutions that were mild and unirritating were found to have no effect in destroying gonococci. There was last year brought before the medical profession by Jadassohn a new chemical compound, composed of a combination of nitrate of silver with casein of milk, called argonin. It is a light powder, soluble in hot water in as high as ten-per-cent. solutions. It is claimed for this drug that it possesses remarkable power to destroy the gonococcus, and it is stated by Jadassohn to have the still further advantage of being absolutely unirritating to the urethral mucous membrane.

The primary attitude assumed by genito-urinary surgeons in general with reference to the merits of any so-called rapid cure for gonorrhea is one of skepticism, and that the writer frankly admits to have been his own position at the beginning of his investigations as to the value of this new drug, so highly lauded by Jadassohn, Lewin, and Meyer.

The earliest contribution to the literature of this subject by an American author is the article in the *American Journal of Cutaneous and Genito-Urinary Diseases*, August, 1896, by Swinburne of New York. This author expresses himself as being "impressed with the fact that the drug was harmless and that it showed marked power in causing the disappearance of the gonococcus."

To my mind the experiments detailed by Swinburne in his "Preliminary Report," in so far as they are supposed to prove the efficacy of argonin in the treatment of gonorrhea, are of very little value, for the simple reason that in every case prior to the use of the daily injection of argonin the urethra was irrigated by a mild solution of permanganate of potash (1:6000).

This use of permanganate irrigations seems to me to have been most unfortunate, for while on the whole his results were satisfactory, it must nevertheless be difficult to state positively whether such results were due to the use of argonin or to the daily irrigations by permanganate of potash.

My own results in the use of this drug are given below, with a full knowledge of how very difficult it is in dispensary and private practise to draw absolutely correct conclusions from statistics. These experiments were conducted at the dispensaries attached to the University Hospital and the Philadelphia Polyclinic. In all the cases careful records were made with reference to the following points:

1. Number of acute cases; number of chronic cases.
2. Time at which the gonococci disappeared after treatment was first employed.
3. Duration of the case, *i.e.*, as far as this point could be satisfactorily determined.
4. Number of cases not at all improved.
5. Number of cases developing epididymitis.
6. Number of cases where discharge returned after apparent cure, and whether such discharge contained gonococci or not.

In conducting these investigations no other drug but argonin was used, and that was ordered in five-per-cent. solution to be used

by the patient as a hand injection; the fluid being held in the urethra five minutes after each injection. Owing to the price of the drug it is impossible to use it in five-per-cent. solution for irrigating purposes.

In total urethritis the solution was employed by the surgeon himself and was introduced into the deep urethra daily, through a catheter.

The number of acute cases treated was 80; chronic cases, 10.

Gonococci disappeared in three days in 4 cases; in five days in 8 cases; in six days in 10 cases; in ten days in 18 cases; in fourteen days in 14 cases; in twenty-one days in 8 cases.

Gonococci persisted over four weeks in 10 cases, and there was an unsatisfactory record in 18 cases.

Apparent duration of the disease: This is the third point noted, and the figures given are approximately correct:

Duration in 8 cases was three weeks; in 20 cases, four weeks; in 25 cases, six weeks; in 20 cases, six to eight weeks.

Record unsatisfactory in 17 cases.

In the fourth point the remedy was of no value whatever in ten cases. It is only fair to state that these were the ten cases of chronic anterior urethritis noted as being under treatment. Swinburne states that he was "impressed with the results obtained in chronic anterior urethritis." In my own hands the drug was of very little if any value in such conditions.

Epididymitis developed in four cases in the fifth point noted.

The records made under the sixth point constitute the most important feature of the investigation. The question of relapse, or return of discharge with or without gonococci after apparent cure, is a most significant one, and one that should receive most careful study before arriving at any conclusion as to the value of a drug in the treatment of gonorrhea.

As regards argonin, Swinburne in his "Preliminary Report" makes the following conservative statement: "The only observations which I have not yet been able to make is the liability of these cases to relapses, and of this a further study must be made."

Out of the eighty cases of acute gonorrhea embraced in this report thirty-two had a return of the discharge after apparent cure; gonococci were found in the discharge in twenty-eight of these cases.

In many of these cases there was an ab-

sence of the discharge for a period of a week or ten days; repeated examinations showed a clear urine, and yet return of discharge followed with reappearance of the gonococcus. The use of argonin would immediately stop the discharge, cause the gonococci to rapidly disappear again, only to break out anew upon discontinuing treatment. All these cases were finally cured by astringent injections.

On the whole the results obtained by the writer in the use of this drug have not been as brilliant as those reported by Jadassohn and other German observers, although they compare very favorably with those reported by Swinburne.

After careful consideration I have arrived at the following conclusions as to the value of argonin:

1. That it is absolutely unirritating and can be used in solutions from one to ten per cent.

2. In the great majority of cases it lessens the discharge very rapidly.

3. Its use is generally followed in a short period by a disappearance of the gonococci.

4. That this disappearance of the gonococcus is not in all cases permanent; in other words there is in quite a large proportion of cases a distinct tendency to relapse, with reappearance of gonococci.

5. That it possesses distinct value as a hand injection in the stationary period of the disease, but is of very little benefit in the mucous stage, or stage of decline.

6. It produced no results in the treatment of chronic anterior urethritis.

The writer would state that he is still using it in his hospital services as an injection in the stationary stage of the disease, and is very much impressed by the remarkable power the drug seems to possess in so many cases of rapidly diminishing the discharge and causing at least a temporary disappearance of all gonococci.

Should the price of the drug ever admit of its being used in irrigation of the urethra it may possibly be found to be of still greater value.

#### *INTERESTING CUSTOMS OF ENGLISH PHYSICIANS WHICH ARE NOW OBSOLETE.*

---

BY J. COLES BRICK, M.D.,  
Assistant Demonstrator of Anatomy, Jefferson Medical College of Philadelphia.

Up until the eighteenth century every physician wore a wig and carried a cane or stick as a badge or insignia of his calling;

and no practitioner would presume to make a call or be seen in public without his mystic wand and powdered wig.

There is something in a stick or scepter which is associated with power or preternatural attributes or authority, which dates back to mythological times. Moses had his rod, with which he struck the rock and the waters gushed forth, Hermes the herald's staff, Mercury the caduceus, Æsculapius his wand, the Roman lictors (hence *licked*) their fasces—down to the mystic bundle of nine twigs, in honor of the Muses, which the famous Dr. Busby used, no doubt to increase the respect of his scholars for them. In the present time the court of St. James has its gold sticks and black rods, the House of Representatives its mace or badge of authority, and even the policeman has his stick.

The physician's cane was long, smooth, and varnished, with a heavy gold knob at the top; and the gold-headed cane which Radcliffe, Mead, Askew, Pitcairn and Baillie successively bore is preserved in the College of Physicians of England. This cane differs from the physician's cane proper, having a cross-bar on the top, while the physician's cane had a knob which was hollow, containing a vinaigrette which the physician held to his nose when approaching a patient, thus protecting him from the poisonous exhalations of the patient. The stick itself was also practically used for the patient to grasp during venesection, tightening and relaxing the hold, thus increasing the flow of blood by muscular action of the arm.

The phlebotomist's staff is of great antiquity; it is to be found in an illuminated missal of the time of Edward I.

Fustigation, or beating with a stick, was believed for many centuries a sovereign remedy for bodily ailments as well as moral failings; and Antonius Musa used this method to cure Octavius Augustus of sciatica. Galen recommended it as a means of fattening. Gordonius prescribed it in certain cases of nervous irritability.

Desault used what he called "club-tincture" on a young man, as related by Sir Astley Cooper, while attending the lectures of Desault and Chopart at the Hôtel Dieu in 1792. A young man was brought in complaining of paralysis of the right arm. Desault, suspecting that the boy was shamming, said unconcernedly, "Take off your hat." The boy instantly obeyed. "Give me a stick," screamed Desault, and he beat the boy unmercifully.

Next to the cane the wig was the most important of his paraphernalia, Dalmahoy being the last to wear one in public. It was a magnificent creation of the peruke-maker's art, and was celebrated in a song of the period. Wadd, the humorous collector of anecdotes relating to his profession, wrote of him:

"Dalmahoy sold infusions and lotions,  
Decoctions, and gargles and pills,  
Electuaries, powders and potions,  
Spermaceti, salts, scammony, squills.

Horse-aloes, burnt alum, agaric,  
Balm, benzoine, blood-stone, and dill;  
Castor, camphor, and acid tartaric,  
With *specifics* for every ill.

But with all his specifics in store,  
Death on Dalmahoy one day did pop;  
And although he had doctors a score,  
Made poor Dalmahoy shut up his shop."

Henry Revell Reynolds, one of the physicians who attended George III, was the last of the silk-coated physicians; he was the Beau Brummel of the Faculty and dressed with the greatest care, refinement, and elegance.

Previous to the reign of Charles II physicians were in the habit of visiting their patients on horseback, sitting sideways, like women. Simeon Fox and Dr. Argent were the last presidents of the College of Physicians to go their rounds in this undignified manner. With "the Restoration" came the carriage of the London physician. In Queen Anne's reign no physician with the slightest pretension to a practise could manage without his chariot and four and even six horses. Although it was only in the reign of Charles II that physicians generally used carriages—though they were used as early as 1563—Stowes' "Survey of London" says of Dr. Langton in that year that he "rid in a car, with a gown of damask lined with velvet, and a coat of velvet, and a cap of the same (such, it seems, doctors then wore), but having a blue hood pinned over his cap; which was a customary mark of guilt, and so came through Cheapside on a market-day." The doctor's offense was one against public morals—he had loved not wisely, but too well.

The cane, wig, silk coat, side-saddle and carriage of the old physician have been mentioned, and his muff we must describe. This was large enough to enclose his forearms and was made of fur, and during cold weather he used it constantly to preserve his delicacy of touch and nice sense of discrimination

when estimating the arterial tension of his patients.

To get some idea of the amount of ignorance of the etiology of disease and of the physiological actions of drugs which physicians possessed during the sixteenth and seventeenth centuries, a glance at some of the prescriptions of Sir Theodore Mayerne, who died in 1655, is sufficient. This man was the most eminent physician of his time, and was physician to two French and three English sovereigns—Henry IV and Louis XIII of France; James I, Charles I, and Charles II of England. He recommended a *monthly excess* of wine and food as a fine stimulant to the system. (In these days this would look like encouraging periodical drunkenness.) His treatise on Gout, written in French and translated into English (1676) by Charles II's physician in ordinary, Dr. Thomas Sherley, recommends a clumsy and inordinate amount of violent drugs. Calomel he gave in scruple doses; sugar of lead he mixed largely in his conserves; pulverized human bones he often prescribed; and the principal ingredient in his gout-powder was "raspings of a human skull unburied." He had a "Balsam of Bats" as an unguent for hypochondriacal persons, into which entered adders, bats, sucking-whelps, earthworms, hog's grease, the marrow of a stag, and the thigh bone of an ox. He also believed in amulets and charms.

Mayerne died in 1655, and two years later Harvey was buried, famous for having discovered the circulation of the blood, the following inscription having been placed on a statue erected in the hall of the College of Physicians:

The circling streams, once thought but pools of blood  
(Whether life's fuel or the body's food),  
From dark oblivion Harvey's name shall save.

Aubrey describes Harvey: "He was not tall, but of the lowest stature, round-faced, olivaster (like waint-scott) complexion; little eie—round, very black, full of spirit; his haire was black as a raven, but quite white twenty years before he dyed. I remember he was wont to drink coffee, which he and his brother Eliab did before coffee-houses were in fashion in London. He was as all the rest of his brothers very cholérique; and in his younger days wore a dagger (as the fashion then was), but this doctor would be apt to draw out his dagger upon very slight occasion. He rode on horse-back with a foot-cloath to visit his patients, his man following on foot, as the

fashion then was; was very decent, now quite discontinued."

In the *Gentleman's Magazine*, vol. xx, for the year 1750, a detailed description and an engraving of a stomach brush may be found, which is in many respects like the *gyromele* now so popular. The idea of the inventor seemed to be based on the principle of the bottle-brush, which was used to cleanse wine bottles before refilling. As we look through the pages of Paret, Sir John Hunter, and other masters of their art, we are led to recall what Solomon said: "There is nothing new under the sun."

#### SURGICAL INTERVENTION IN TUBERCULOSIS OF THE KIDNEYS.

TUFFIER reports fifteen operations performed on the kidneys for tuberculosis, about a tenth of his operations on these organs (152 in all), in the course of the last eight years. He only operates when all medical treatment has been found ineffective, and considers the three principal indications: intense hematuria, pains and evidence of infection, and intoxication. Benign hematuria does not require intervention, but only severe cases, with sufficient loss of blood to weaken the patient to a dangerous degree. He has operated twice under these conditions. The first was a woman of forty-two, with dangerous crises of hematuria and consecutive anemia, on whom he performed nephrectomy. The ablation of the left kidney disclosed a number of tuberculous abscesses in the parenchyma. The patient has never had a recurrence of the symptoms, and when seen three and a half years afterward was in perfect health. The other case was a woman of twenty, with severe hematuria for three years previously. After lumbar incision, and the discovery of a voluminous kidney, he performed nephrotomy, and the patient continued eighteen months without a recurrence of the trouble. Since then she has had slight returns of it at times, but not enough to warrant another intervention.

Tuffier has performed four operations to relieve excessive pain. The first case was a woman, whose sufferings had much reduced her. The kidney was found riddled with tubercles, and removed; the ureter seemed intact. She recovered finely, and when seen five years later was still in perfect health. One peculiarity of this case was the sudden appearance of obesity after the operation, which assumed such proportions as to be

actually pathologic; this also occurred with another patient. This condition gradually passed away.

The second operation to relieve pain was performed on a young Russian woman, who had been examined by Billroth of Vienna, Wood of London, and Erb, all of whom at first ascribed her troubles to neuralgia, and later to lithiasis, as did also Senator and Israel at Berlin. Finally Gennes discovered the Koch bacillus in the urine, and Oertel at Munich and Czerny confirmed the diagnosis of tuberculosis, and advised an operation after the whole range of local applications had been tried in vain. Her renal pain was so severe that it was impossible for her to walk, and there was also frequent desire to urinate. Morphine alone relieved her. The pain dated from a fall in 1892, after which she had suffered from pain in the kidneys, with frequent crises, becoming worse and worse. Tuffier performed nephrectomy by the lumbar route January, 1896, freeing the patient from her troubles. The ureter was found dilated and granulous, and by the end of the year, the desire to urinate returning, she consulted Israel again, who found by cystoscopic examination a tuberculous patch at the entrance of the ureter, showing descending infection.

A third patient was operated upon and restored to health, except for a slight frequency of mictions and trifling hematuria. When a calculus forms the pain is atrocious, and in one case had driven the patient, a former pupil of his, to morphinomania. The calculus was the size of a large nut and was found in the lower end of the ureter. The suffering had undermined the patient's health to such a degree that he did not long survive the operation.

Tuffier has performed nine operations to relieve the accidents of tuberculous pyelonephritis, acute or chronic; but these operations are merely palliative and with the sole hope of affording temporary relief. They emphasize anew the importance of operating at once when the diagnosis has been established with certainty. He advises nephrectomy as preferable both in the hematuric and painful variety. His experience certainly demonstrates the existence of primary renal tuberculosis, which some have denied; and the perfect health of some of his patients, operated on four, five, and six years ago, is conclusive evidence of the value of intervention in these cases.—*Journal of the American Medical Association*, March 20, 1897.

### THE CURATIVE INFLUENCE OF PARACENTESIS UPON HEPATIC CIRRHOSIS.

If there is one condition of the liver associated with organic change and with which we associate in our minds the presence of an incurable affection, it is that which is known as hepatic cirrhosis, particularly when it is associated with grave secondary changes in the abdominal organs or in more distant portions of the system. A large proportion of the cases of marked ascites which present themselves for relief in hospitals and private practise depend upon this lesion of the liver, and physicians are universally in the habit of attempting to remove this effusion with the object of relieving the patient's distress and discomfort, but with little thought that in getting rid of the fluid they are accomplishing anything more than very temporary relief. A careful study of a series of such cases convinces us, on the other hand, that if the fluid is removed by means of paracentesis the general tendency of this treatment is to

prevent the reaccumulation of the liquid; and further than this, by the removal of pressure exercised upon important organs it improves the patient's condition and perhaps even modifies the pathological process which has taken place in the hepatic tissue. Our attention has once more been called to this matter by a paper by Dr. Chandra Sen which is published in the *Indian Medical Gazette* for April, 1897. In this article he mentions two cases which entered the wards of the hospital with which he was connected and were treated by the ordinary diuretics and purgatives, with but little advantage until they were tapped, immediately after which procedure they began to improve. In neither of them did the effusion recur, and the patients were living many months after the last tapping.

Dr. Sen is wrong, however, in his statement that this method of treatment and these results are new. It has been a well recognized fact for many years that in a certain proportion of cases the effusion when once removed does not return, but what is still more important and what has not been recognized as completely as it should be is the fact that the tapping exercises a distinct beneficial influence over the patient's general condition. This point was emphasized several years ago in an article which the writer of this editorial published in the THERAPEUTIC GAZETTE, in which he discussed the arguments which have been advanced for and against paracentesis abdominis, and showed that modern methods and modern views were very distinctly in favor of removing serous effusions by tapping rather than by the older methods of purgation and the production of excessive diuresis.

MacDonnell of Montreal was during his lifetime one of the most earnest advocates of tapping for cirrhosis, and he reported in the *Medical News* for October, 1889, the case of a butcher who had been tapped repeatedly, sometimes as frequently as every two days, and from whom no less than 6400 ounces of fluid were withdrawn in about four months for ascites due to alcoholic cirrhosis. The fluid gradually failed to accumulate, and to the surprise of MacDonnell the patient practically recovered in the course of a year, becoming a hearty man. In the same article MacDonnell also quoted another case in which nine thousand ounces of fluid were withdrawn, and after this complete restoration to health took place. It is evident, therefore, that paracentesis abdominis offers more to the patient than the mere removal

of fluid which by reason of its pressure is causing discomfort and interference with the respiration, circulation, and digestion.

---

*THE EFFECT OF ANESTHETICS UPON  
BODILY TEMPERATURE.*

---

On several occasions in the editorial columns of the *THERAPEUTIC GAZETTE* we have called attention to the importance of maintaining bodily temperature by the use of the external application of heat in surgical operations during the time that an anesthetic is being administered, and as long ago as 1888 the writer of this editorial published in the May issue of the *GAZETTE* for that year an article upon some experiments to determine the influence of etherization upon normal bodily temperature.

With reference to the use of external heat, in this paper it was found that in a series of twenty-six cases the administration of ether caused a very marked fall in bodily temperature. Thus in one series of cases the average fall of temperature was from  $2.5^{\circ}$  F., the greatest fall being  $4.4^{\circ}$  F., and in another series in which the temperatures were taken in patients who were under the surgical care of the late Dr. D. Hayes Agnew it was found that the fall of temperature amounted on an average to  $2.32^{\circ}$  F., the greatest fall being  $3.15^{\circ}$  F. These temperatures were taken in the rectum, the previous ones named having been taken in the axilla. The operations varied in all degrees of severity.

Our attention has been directed to this matter anew by a paper which has been published in the March number of the *American Journal of the Medical Sciences* by Dr. Allen of Cleveland, in which he details the results of a number of experiments which he made upon dogs to determine what influence etherization had upon their blood-pressure and bodily temperature. The results which he obtains are practically identical with those which the writer of this editorial obtained nine years ago, but there is one possibility of error in his conclusions which we think has been overlooked, namely the fact, well known to those who have worked with animals in the physiological laboratory, that placing a dog upon his back with the limbs fixed in the manner usual when making an experiment always results in a considerable fall of temperature, unless the bodily heat is maintained by a covering or by applications of heat. In other words, an animal lying exposed upon a

table and absolutely uninjured and not receiving any anesthetic will have a very considerable fall of temperature in the course of one or two hours. We believe that the custom of covering the patient with a very small amount of clothing during an operation and exposing large portions of the cutaneous surface to the air during the operation greatly increases the danger of secondary bronchitis and congestion of the important viscera, particularly the kidneys; while many physicians exclaim at the imprudence of the patient or nurse if they found the patient was lightly covered when lying in bed under ordinary circumstances, though they permit almost no covering at all during a prolonged and exhausting operation accompanied by serious shock to the vital centers.

We are glad that Dr. Allen has once more called attention to this important fact, upon which we do not think that too much emphasis can be placed. During the operation the patient should be more warmly covered than when lying in bed prior to the operation, and if external heat properly applied is used during operative procedures the loss of heat will be prevented, and the old saying about the door being locked after the horse is stolen will not find a daily illustration in the surgical amphitheater.

---

*INTRAVESICAL INJECTIONS OF STERILIZED AIR FOR TUBERCULAR CYSTITIS.*

---

One of the most interesting developments of modern surgery has been the fact that the opening of the abdominal cavity when the peritoneum and viscera are affected by tuberculosis results in cure in a large proportion of cases. At first it was thought that the iodoform which was usually dusted into the abdominal cavity under such circumstances was entirely responsible for the good results which were obtained, but it was not long before it was found that the introduction of air through an opening which had been made was distinctly curative in its effects. Following this certain operators with more or less good result treated cases of tubercular peritonitis, not by making an incision in the abdominal wall, but simply by introducing a cannula and injecting sterilized air into the peritoneum. More recently our attention has been called to a new application of this method of treatment. Thus Ramond has treated three cases of tubercular cystitis which otherwise seemed

incurable by the injection of sterilized air into the bladder. The method of procedure is as follows: The instruments and the catheters are carefully sterilized, and a syringe such as is used for tapping hydrocele and having a capacity of three ounces is employed. Over the mouth of the syringe is placed a small tampon of cotton so that the air from the barrel of the syringe as it enters must be filtered through the cotton. The urine having been evacuated, three ounces of sterilized air are injected by means of a hollow sound, and future injections of from six to nine ounces are given with considerable force. The air injected is allowed to remain in the bladder for a period of five minutes, when it is allowed to escape by means of the sound. Should pain be produced by this method the operation is not resorted to again for two or three days.

The question as to how this treatment is of advantage is scarcely possible to answer. The air may have some deleterious influence upon the tubercle bacillus, or some favorable influence upon the inflammatory processes associated with its presence. In any event Ramond is enthusiastic in urging its employment, particularly in those cases which refuse operation or are too feeble to have any operation performed.

---

#### INCONTINENCE OF URINE IN CHILDREN.

---

The difficulty in overcoming certain cases of incontinence in children is recalled by a somewhat elaborate, well-systematized paper by Rochet and Jourdanet (*Gazette des Hôpitaux*, January 9, 1897) who classify cases of incontinence in children under two general headings:

1. Those in which incontinence is the expression of a distinct local lesion, or those in which it develops in the course of a general disease, of which it is an expression of minor importance. Such forms of the disease are called symptomatic. The appropriate treatment is that directed to the general condition, as post-typhoidal adynamia, or to the local exciting cause, as a rectal polyp or balano-posthitis.

2. Those in which incontinence is the only symptom. Such cases are called essential, though in reality they more correctly would be named neurotic. The term "incontinence" is misleading, since this implies a constant dribbling; whereas in children it nearly al-

ways assumes the form of involuntary urination.

The essential incontinence of children is always associated with a neurosis, usually hereditary; indeed Guyon considers wetting the bed a pathognomonic sign of this condition. It may be, perchance, the only sign, though it is often associated with other manifestations even more characteristic.

The condition itself may be directly brought about by undue contractility of an irritable detrusor muscle, or by hyperesthesia of the mucous membrane of the prostatic urethra, or by thoughts or ideas which produce frequent urination by day and incontinence by night.

In the class of cases in which the neurosis is manifested in the form of spasm of the vesical sphincter, this may result in either partial retention, which necessarily favors wetting of the bed, or of complete retention, which would cause a true diurnal and nocturnal dribbling (retention with overflow). Very exceptionally the neurosis may be expressed in the form of a paresis of the sphincters; this also would give rise to constant dribbling. In examining patients it is important to bear in mind the possibility of retention with overflow. This condition would be detected at once by catheterization, and if the injected fluid were returned through the catheter with slight force the surgeon would at once suspect paresis in the detrusor muscles. The introduction of a catheter will also detect atony or hyperesthesia and spasm of the ureteral sphincters.

In case urethral exploration remains negative abnormal sensibility to distention would be suggested as a possible cause of incontinence. Injection into the bladder would at once settle this question, since the viscus if hypersensitive to tension would reject the liquid when but a small amount had been driven in. In case exploration remains negative the incontinence may be classed as psychic.

The treatment should, of course, be primarily that applicable to neuropathies. Belladonna is particularly indicated in those cases which are probably due to an over-excitability of the detrusor muscles of the bladder. No one has been able to suggest a better means of administration than that first proposed by Trousseau. The initial dose is one-sixth of a grain of the extract given in the evening at bedtime. After several days this dose is doubled, the patient finally taking as much as from one-half to one grain, the surgeon carefully watching for toxic symp-

toms and stopping the medicine very gradually if the desired effects are obtained. Other medications possibly serviceable in the same condition are bromides, chloral, camphor, lupulin, lactucarium, and opium.

When the cause of incontinence is immediately traceable to a hyperesthetic condition of the mucous membrane of the posterior urethra, general sedatives are still serviceable. Local treatment is, however, especially indicated, instillations of cocaine or of silver nitrate and the repeated passage of a cold full-sized sound being particularly useful.

The very rare cases of incontinence due to anesthesia of the urethro-vesical region, practically always due to lesions of the spinal cord, are said to be benefited by cauterization of the posterior urethra. Trousseau's advice for atony of the vesical sphincters is that strychnia should be given in fairly full doses morning and evening, continuing the medicine for two days and then allowing two days of rest. The quantity of the drug is gradually increased. Guyon in this class of cases has been particularly successful with electricity. An electrode is introduced, insulated excepting at the end. The other electrode is placed either upon the pubis or the lumbar spine, and the faradic current with slow interruptions is employed. Each treatment should last about five minutes; this directly exercises the weakened muscles and restores their tonicity. To control the psychic influences, especially the dream of micturating, various means are serviceable. Thus, the slumber may be rendered less profound by means of tea or coffee. These agents are, however, not to be commended in the treatment of neuropaths. Another method is to wake children regularly during the night. This method gradually accustoms the bladder to regular evacuations. The number of wakings should be proportionate to the quantity of urine secreted and to the frequency of micturition during the day. Punishment is successful in some cases, since it makes a powerful impression upon the brain. Suggestion has been utilized in other ways: thus painful subcutaneous injections have been employed, or operations have been threatened. Finally hypnotic suggestion has been used, Liebeault having claimed by this to have cured cases. The first step in this treatment is to procure hypnotic sleep. It is then suggested that the child should rise at certain hours to urinate; gradually the number of risings by night is diminished until finally they are abolished entirely, the child

being forbidden to urinate until it wakes in the morning.

The pure psychopathic incontinence dependent upon dreaming of micturition is probably the most troublesome of all to cure. Psychic treatment is alone efficient. The cure is usually spontaneous in these patients and accomplished about the time of puberty, when amorous dreams replace those of micturition. These patients often become congenital hypochondriacs who swell the ranks of those who suppose themselves suffering from spermatorrhea, and who after gonorrhoea hypnotize themselves concerning the urethra and are thus able to see a constant discharge of semen.

The cases of incontinence due to retention of spasmodic origin are readily cured by the regular passage of catheters and sounds. Once daily the bladder is completely evacuated. Once or twice a week full sized sounds are passed after the catheter. Treatment is continued for about a month, amelioration is usually rapid, and the cure complete. Should incontinence of overflow result not from spasm of the sphincter but from paresis of the detrusors, the only treatment would, of course, be faradization.

## Reports on Therapeutic Progress

---

### SULPHUR IN SEPTIC AND TUBERCULOUS SORES.

MILLER writes on the use of sulphur externally in the London *Practitioner* for February, 1897. He urges its use in surgery, and begins by telling us that sulphur is non-poisonous. This might go without saying. The drug and its products seem to act only locally, and there is no general effect on the patient that the writer has seen; but he has used it only in small quantities.

Sulphur applied to a recent wound or granulating surface gives rise to various chemical products—sulphuric acid, sulphurous acid, and sulphureted hydrogen. These are probably all caustic, the first most powerfully; they are all germicidal, doubtless also in varying proportions. The presence of two of these products is manifest to the sense of smell. In a few hours after the sulphur has been applied there is a distinct odor of sulphureted hydrogen and of sulphurous acid. If sublimated wool is employed as part of the dressing the presence of the former is also made evident by the blackening of the wool. The sulphuric acid manifests its pres-

ence mostly by its caustic action. Any sloughing that occurs is most likely due to its action, as stated by Mr. Lane.

It is by its products therefore, and not directly, that the sulphur acts on the tissues. Mr. Lane says that the products of sulphur are so powerfully caustic that the drug must be used "in small quantities and with discretion." His reported cases show this. The writer confirms this statement. He has only twice used the drug freely. In both cases there was a good deal of pain produced of a burning character, though without any rise of temperature, and there was considerable sloughing. Though no harm ultimately resulted from the sloughing, yet the writer thinks it was unnecessary. In one case the burning pain and sloughing continued for some hours after all trace of the sulphur had been removed by washing out the wound. The cases were excisions of the elbow and ankle respectively for tuberculous disease with septic infection.

The sulphur products are germicidal. The sulphur, therefore, is a powerful antiseptic. Mr. Lane says that it destroys all organisms, both "free in a cavity" and also in the tissues. This the writer confirms. In his experience the sulphur destroys very thoroughly both septic and tuberculous organisms. And as we know that these, more especially the latter, tend to penetrate the tissues, the production of a healthy surface on wound or sore must mean that the germicidal agent has penetrated somewhat into the tissues also. It is easy to see how this may occur. The sulphur lying in contact with the tissues undergoes chemical change; the gaseous products pass off into the dressings and in the discharge. That they do so is evidenced by the smell to which the writer has already referred, and by the blackening of mercurial dressings. The sulphuric acid, however, acts on the tissues more directly and cauterizes them, doubtless at the same time destroying any organisms with which it may come in contact.

Now one might say, Why not use sulphuric acid alone and directly, seeing it is the most powerful and important agent, and not the sulphur, which gives rise to other and unpleasant products also?

There are two special advantages in the way that the sulphuric acid is produced from the sulphur: Only a small quantity is produced at a time, and the caustic action can therefore be regulated; in the second place the production is gradual, going on for a considerable period, and therefore is more

powerfully germicidal. Sulphuric acid applied directly, however dilute, would at once act on the tissues and spend itself in its caustic action; it would penetrate to a certain distance according to the strength and amount of acid applied, but its action would then quickly cease. On the other hand, in the case of the sulphur application, we have a continuous action going on for many hours—sometimes for two or three days—with very little caustic action. In a word, with the acid we would get the maximum of cauterization and the minimum probably of germicidal action, while with the sulphur and the continuous formation during many hours of its chemical products the result is most likely the other way. It is possible also that the two other products are more powerfully germicidal than caustic, and they may penetrate the tissues also. Whatever is the explanation, however, the fact remains that wounds treated with sulphur quickly become aseptic, and tubercle bacilli also seem to be destroyed in them.

The action of sulphur is more powerful on recently incised wounds. This requires neither illustration nor comment, except that surgeons should be very careful in applying the sulphur in operation cases. The writer is inclined to think that children's tissues are specially easily cauterized; anyway, children more frequently complain of the burning pain than adults.

The action of sulphur is mitigated by mixing it with glycerin. Such a mixture, therefore, with the addition perhaps of some carbolic lotion, makes a good injection for septic or tubercular cavities. The constituents are common and easily obtained, and can be readily and quickly mixed by any one.

With Mr. Lane's last point, that twenty-four hours is generally quite sufficient time for the sulphur to produce its destructive action in a recent wound, the author agrees; but in septic and tuberculous sores a longer period is necessary. Each case, however, must be judged by the effect of the applications. In his experience two or three applications have been usually sufficient to produce a healthy and healing surface. He then concludes his paper by describing how the sulphur may be applied:

On an open surface, whether of a recent wound (as at an operation) or of an ulcer, the sulphur in fine powder should be gently rubbed in with the finger, and the wound or sore dressed with an antiseptic dressing. No effect is produced on the surgeon's fingers whatever.

In the case of an abscess or other septic or tuberculous cavity the sulphur is injected suspended in glycerin (one drachm to one ounce).

The consequences have been already described: first, a slight burning pain; second, a strong-smelling discharge (from the gaseous products of the sulphur); third, a slough, varying according to the character of the wound (recent or granulating) and the amount of sulphur applied; and lastly, there is the therapeutic (germicidal) action. The burning feeling, if complained of, can be mitigated or removed by cocaine. As a rule, when the slight slough produced by the sulphur separates (in a day or two) healthy granulations are manifest, and the writer not infrequently has seen sores heal in a week or two that had resisted all other treatment for months.

Mr. Lane mentions in his papers having used this drug in cases of cancerous and sarcomatous ulceration and stomatitis with benefit. He states that he can say nothing on these points, not having employed the "sulphur cure" in such cases.

#### *THE ADVANTAGES IN THE TREATMENT OF SYPHILIS AT THE HOT SPRINGS OF ARKANSAS.*

In the *Journal of the American Medical Association* of February 6, 1897, HAY writes of these important Springs and describes their characteristics. In regard to the local methods of treatment he tells us of the patient that he is first instructed as to his diet, which is to stop eating all sweets and acids; his mode of living, which is to keep regular hours; stop smoking and chewing if addicted to the use of tobacco; and abstain absolutely from the use of all intoxicating liquors. The next step is prescribing his medicines and baths. The inunction method is used almost exclusively by the physicians at the Springs, taking the official fifty-per-cent. ointment and usually dividing an ounce into eight, six, or four papers, and rubbing in the contents of one paper each day, according to the exigencies of the case.

The bath is then prescribed, and the general routine for the day is as follows: The patient arises at 7 A.M., breakfasts at eight, then allows from two and one-half to three hours to elapse so that digestion is thoroughly established; goes at 11 A.M. to his bath, which consists of immersion in the hot water contained in porcelain-lined tubs from six to twelve minutes at a temperature from 94° to

96° F.; at the completion of which he is thoroughly rubbed down by his attendant until the skin glows from the stimulation of the peripheral circulation. He is then wrapped in his bath robe and passes into a lounging-room that is kept at a temperature of 90° F. He remains there from thirty to sixty minutes; and it is while in this room that the inunction of mercury is applied while the skin is active and the pores open, in the following manner: The patient sits astride of a straight-back chair with arms folded over chest and back exposed; the attendant with his hands encased with rubber mittens spreads the ointment over the entire surface of the back; then standing by the patient's side, with a long sweeping motion, exerting an equable pressure, distributes the ointment evenly, and continues until the back seems to become quite dry, which takes generally ten to twenty minutes, depending on size of inunction. The patient then puts on a light gauze shirt called the "mercury shirt," which is worn constantly under his other garments and is never washed or discarded until he has finished his course. This naturally in the course of a week or so becomes quite well saturated with the ointment and is the source of constant absorption. The patient then passes into another cooling-room kept at a temperature of 80° F., and after remaining thirty to forty minutes returns to his room and lies down before luncheon for about one hour, and he has finished for the day. If iodide of potassium is administered it is generally given in the saturated solution or fifty per cent. with some adjuvant like essence of pepsin. The writer himself prefers the fifty-per-cent. solution, and uses essence of pepsin, as it protects the stomach, aids digestion, and you do not witness any of the disagreeable gastric symptoms like those produced by the saturated solution alone. Diaphoresis is not encouraged in the bath during the inunction course, because as the emunctories are filled with mercury any excessive sweating would expel what we want absorbed. After saturation is produced the mercury of course is discontinued, at least until the symptoms all subside. About five or six days before the patient takes his departure for home he is instructed to take about as many vapors in addition to the plain baths, which are detailed as follows: Plain baths ten minutes at 100° F.; then placed in a vapor closet for five minutes, standing in a vapor arising from water at about 150° F. He is then released and

passes into the hot room kept at 120° F., and remains from five to ten minutes. While in the bath and hot room he is instructed to drink the hot water freely. After passing through this you can well imagine the perspiration must be flowing quite freely. He is then removed to the first cooling-room above referred to, kept at 90° F., wrapped up thoroughly in his bath robe, and allowed to cool off. The day before departure, especially if the patient lives in a cooler climate, a plain warm bath is administered, and followed by an alcohol sponging to close the pores.

This is a complete synopsis, as briefly as the writer can state, of the methods.

Before closing he speaks of the administration of mercury and iodide of potassium. There is no place on this continent where such enormous doses of either of these drugs can be given and produce such slight and mild constitutional disturbances as at the Springs. Patients frequently come here who cannot take specific treatment at home, and tolerate both mercury and potassium while taking the baths without suffering any inconvenience. As high as 1000 grains of iodide of potassium have been given in a day at the Springs. The writer recently had a case of cerebral syphilis in which he administered 600 grains a day, the patient's appetite remaining good, bowels regular, and the drug producing only the ordinary weeping of the mucous surfaces.

That these waters do possess superior solvent and eliminative properties he contends. It is a common experience to have patients present themselves suffering from the baneful effects of mercury, gums tumefied, eroded, and bleeding upon slightest pressure, when by the administration of a few vapor baths the inunction course can be instituted and continued without any distress. But a great many of these cases are not due to saturation, but to their former physician's neglect of observing the condition of the teeth before starting them on a course of mercury; and the stomatitis is of local origin caused by the accumulation of tartar or a decayed tooth. Their system is not under the influence of mercury at all, and can instantly be relieved by sending them to a dentist. The reason why such large doses of mercury and potassium can be tolerated at Hot Springs is due to the important part the skin takes in the elimination of these drugs. This is a fact discredited by a great many physicians and ridiculed by not a few; but the

author believes it is equally as important as the kidneys.

Ronovitch in 1895 made a series of experiments upon a number of patients to whom mercury was being administered in some form. "A Roman hot bath was used for twenty minutes to induce perspiration, and equal quantities of sweat and urine were used for examination. He concluded that the elimination of the drug through the perspiration is much greater than has hitherto been supposed. A relatively larger quantity was excreted by the sweat than by the urine, but this only in cases where mercury was introduced into the system by friction. This the author explains by the retention of the drug in the sudoriparous glands, friction causing it to be pushed into the glands before it had time to enter the circulation; but the quantity was the same in the sweat and urine of patients treated by injection."

#### SALINE INJECTIONS.

LOCHELONGUE (*Thèse de Paris*, No. 6, 1896-97) traces the history of this treatment from its introduction by Joehrnichen of Moscow in 1830 to its discussion in the Academy of Medicine and Society of Biology last year. In infectious diseases the injections are invariably followed by a well-marked rigor like that of pneumonia, the temperature rises, perhaps to 105.4° F., with a quick pulse and panting respiration. These symptoms generally improve, perspiration sets in freely, and in from three to four hours a feeling of comfort supervenes, the headache disappears, the temperature rapidly falls to normal, the emunctories become active, and a veritable polyuria, or occasionally a profuse diarrhea, is established. If this improvement be not permanent another injection generally makes it so. Unhappily the system is sometimes so profoundly infected that death is hardly, if at all, postponed. The experiments hitherto made do not warrant any conclusions as to the action of these injections in intoxications. Nevertheless in typhoid fever, scarlatina, etc., as well as in diabetes, uremia, and paroxysmal tachycardia, they have been followed by improvement of the general condition, lowering of temperature, abundant diuresis, and increase of blood-pressure. In general the subcutaneous method is to be preferred. Venesection may precede the injection, and is indicated in uremia.

MOURETTE (*Thèse de Paris*, No. 40, 1896-97) points out that intravenous injection of saline

fluid ameliorated the condition of a patient of Delbet's whose heart was apparently at fault, and that a typhoid patient of Widal's, twice benefited by a subcutaneous injection, succumbed during an intravenous one; he also mentions a fatal case of Chauffard's from the same cause. He concludes that intravenous injection should not be employed if it is possible to wait for an hour or two; subcutaneous injection, though slower, is equally sure, and from it no accident has been reported.

FORMEAUX (*Thèse de Paris*, No. 82, 1896-97) discusses the subcutaneous method very fully, both from the experimental and the clinical point of view, and gives a detailed and illustrated description of the technique. He agrees that the subcutaneous method is as efficient and less dangerous than the intravenous, and advocates the injection (about 600 grammes) as often as may be indicated during careful observation day and night in diffuse hemorrhage; fever is no contraindication; hypothermy is not to be feared. Moreover, they may be used before or after operation on anemic subjects by the surgeon, and should be in readiness during any intervention that is likely to be protracted. As a general tonic before, and more especially after, operative treatment a daily injection of a more concentrated solution—two per cent. of neutral phosphate of soda (Crocq)—may be employed. In grave asthenia Cheron injects every two or three days five to ten grammes of a solution containing one part of crystallized carboic acid and two of chloride, eight of sulphate, and four of phosphate of soda to 100.

BARBIER (*La Semaine Médicale*, 1896, p. 488) reported to the Société Médicale des Hôpitaux that in intestinal infections of children at the breast a 7-5 per mille solution injected under the skin of the abdomen, in quantities not exceeding in all thirty cubic centimeters in the twenty-four hours, apparently stimulated the entire system by increasing the blood-pressure and raising the temperature; and patients in a state of collapse, with pinched nose, half-closed eyes, and cold extremities, rallied after one or more injections. The treatment seems to him to be indicated in infectious enteritis with hypothermy, and in chronic cases with loss of strength and low temperature, but has no effect on the diarrhea, general nutrition, or any pneumonia other than those of collapse.

HAYEM says that while the injection of saline solution is one of the most powerful means

of restorative treatment, and is indicated in all choleric conditions, it would hardly have any beneficial influence on gastro-intestinal dyspepsias.—*British Medical Journal*, Feb. 14, 1897.

#### HASHEESH (*CANNABIS INDICA*) AS A CAUSE OF INSANITY.

HYSLOP gives a review of Mental Diseases in the London *Practitioner* for February, 1897. In its course he remarks that hasheesh as a cause of insanity is the subject of a valuable report by Dr. Warnock, the medical superintendent of the Cairo Lunatic Asylum. He concludes that no doubt in quite a considerable number of cases hasheesh is the chief if not the only cause of the mental disease. Hasheesh insanity can scarcely be diagnosed by its clinical characters alone. Sudden and rapid recovery on abstinence from the drug is the most pathognomonic symptom. He classifies the usual types of hasheesh insanity as being: (a) Hasheesh intoxication: An elated, reckless state, in which optical hallucinations and delusions that devils possess the subject frequently exist. Sometimes the condition amounts to a delirium, which is usually milder, more manageable, and less aggressive than that of alcohol, and exhibits none of the ataxic phenomena of the latter. Recovery takes place in a day or less, and the patient usually recognizes the cause of his excitement. In connection with these cases Dr. Warnock raises the interesting medico-legal question, "Are such patients to be held responsible for crimes committed during the hasheesh intoxication, as ordinary drunkards are? or are they absolved from responsibility, as being temporarily insane? Persons chronically insane from drink are held to be irresponsible for criminal acts, temporary intoxication on the contrary being no plea. Will the same principle be applied to hasheesh crimes?" (b) Acute mania: In this type terrifying hallucinations, fear of neighbors, outrageous conduct, continual restlessness and talking, sleeplessness, exhaustion, marked incoherence, and complete absorption in insane ideas, are the prominent symptoms. Such cases last some months and do not always recover. (c) Weak-mindedness with acute outbreaks after each hasheesh excess: These cases are very numerous. While in residence such patients are usually quiet and well behaved and only betray the impaired state of their brains by being over talkative, easily pleased, lazy, anergic, excitable on small

provocation, unconcerned about their future, and willing to stay in hospital all their lives; they show no interest in their relatives, and only ask for plenty of food and cigarettes. After being discharged such cases soon return in a condition of excitement—in fact, in a mild form of type *b*. They then talk rapidly, and rush about pouring torrents of abuse on those near them, curse and rave on slight provocation, are sleepless, and forever moving in an aimless way; are urgent to be released, deny the use of hasheesh at one moment and boast of its wonderful effects the next. Besides these types there are numbers of cases of chronic mania, mania of persecution, and chronic dementia, alleged to be produced by hasheesh.

Dr. Warnock also quotes some of the conclusions of the "Indian Hemp Drug Commission" of 1893-94. Its moderate use has no physical, mental, or moral effects whatever; its excessive use, on the other hand, injures the physical constitution, and may cause dysentery and bronchitis; it tends to weaken the mind, and may sometimes cause insanity; it induces mental depravity and poverty, but rarely crime. The injury caused by excessive use is confined almost exclusively to the consumer, and scarcely affects society. In India hemp drugs are regarded as causing insanity more rarely than has popularly been supposed, and the resultant insanity is usually of a temporary character and of shorter duration than that due to other causes.

---

#### OPERATION FOR PERFORATION IN TYPHOID FEVER.

An extremely interesting discussion recently took place at the Royal Medical and Chirurgical Society on the operative treatment of perforation in enteric fever. Two papers were read on two cases, on each of which Mr. Bowlby operated. Both the patients were convalescent and both recovered. In Dr. Lauder Brunton's case perforation occurred, but the symptoms were not nearly so severe or so suggestive of perforation as in Dr. Herringham's patient, in whom laparotomy revealed the fact that there was no perforation, peritonitis, or other apparently sufficient cause for the extreme gravity of the symptoms. The colon was packed with scybala, and this appears to have been the cause, for they were removed by enemata directly the operation was over, and the patient straightway recovered. Constipation and subsequent colic must therefore be borne in mind

as a possible cause of alarming symptoms, and should render caution necessary in allowing long-continued inactivity of the bowels to occur in typhoid fever; for such a course may bring about results closely simulating the accident (perforation) which prompts its adoption. The two cases form a striking contrast, and seem not only, as Dr. S. Phillips pointed out, to emphasize the difficulty of diagnosing with any certainty whether perforation has or has not taken place, but also to throw doubt on the view that perforation may be recovered from spontaneously. In Dr. Herringham's case the symptoms justified an emphatic diagnosis of perforation, and had not operative proof that no perforation existed been provided it would fairly have been regarded as a case in point.

Mr. Shield referred to an interesting case in which the symptoms of perforation of the bowel occurred after typhoid fever, but were found to be due to perforation of the gall-bladder.

Both the patients referred to in the papers were convalescent and in good condition, and therefore bore the operation well; and it is in such cases, as Dr. Goodall pointed out, that operative measures may be expected to succeed. But it must be borne in mind that the majority of cases of perforation in typhoid fever are met with during the course of the fever when the patient is in a most unfavorable state for operation. Cases for operation, therefore, must be carefully selected, or the operation, on which Dr. Brunton and Mr. Bowlby are to be sincerely congratulated, will be discredited rather than established.—*British Medical Journal*, Feb. 14, 1897.

---

#### ON THE TREATMENT OF ECZEMA IN CHILDREN.

BULKLEY, the well known dermatologist of New York, contributes to the *Archives of Pediatrics* for February, 1897, a very practical paper on this topic. He begins by asking the question: "Does it ever do harm to cure an eczema?" In answer to this the writer says that in his practise of over twenty-five years he cannot recall a case where harm resulted from the proper treatment of an infantile or other eczema. Among 10,000 miscellaneous skin cases in his private practise, recently analyzed, there were 3201 of eczema, and of these 375 were under five years of age. Many of these cases have been watched for years, and are only improved in health by the proper cure of the eczema.

"To what extent should constitutional treatment be relied on?" Constitutional treatment, including diet and hygiene, is the main reliance as to the cure of a large proportion of the cases of eczema in young children. While in a certain small proportion the eruption may be almost wholly local in nature and origin, and yield to local measures and then remain absent, in the larger proportion it will tend to crop out again and again unless proper constitutional measures are taken.

"Is eczema the result of a diathesis?" This was the opinion of many dermatologists some years ago, but at the present time it is difficult to define scientifically in what a "diathesis" consists, and he thinks that very few now hold to any fixed diathesis as a cause of the eruption.

"What are the predisposing causes?" Primarily, debility of tissue, which may be either hereditary or acquired; secondarily, very many internal causes may be classed under (1) Dietetic, (2) Assimilative, (3) Neurotic; and the external under (1) Climatic, (2) Hygiene. The limits of this article forbid any full discussion of these topics (which might be very extended) or of the consideration of the various exciting causes of eczema; but a brief explanation may be offered of some points relating thereto. Local irritants, however severe, are incapable of exciting true eczema, except in those so predisposed; a dermatitis or superficial inflammation may be excited, presenting many of the characteristics of the eruption under consideration, but it is quite different in its tendency to speedy recovery when once the local cause is fully removed and the surface is adequately protected.

A most striking illustration of the difference may be seen in scabies, where in the large majority of cases the eruption, however severe it may have been made by scratching, will cease with the proper local treatment of the parasitic disease; but in a few cases the local irritation thus set up will not so subside, but will continue and spread, exhibiting pronounced features of true eczema. The distinction should be clearly made between a local dermatitis (from the very many causes) and real eczema; if this were always done the proportion of eczematous cases would be smaller.

"To what extent does it depend on diet?" To a very large extent. By this is not meant that any one or many articles of food may or can produce the tendency to eczema; but it

does mean that faulty nutrition of the tissues, largely due to dietary errors, plays a very considerable part in the production of eczema. Other things being right—that is, the functions being all well performed, etc.—with a perfectly correct or ideal diet and nutrition the skin tends to be perfectly formed, and does not tend to take on a catarrhal tendency under local or even internal irritation. But with an imperfectly nourished skin this readily takes place, especially in those with an inherited or constitutional tendency to the same.

"To what extent is diet to be relied upon in treatment?" Very largely, in conjunction with proper internal and external therapeutics. Not only are articles known to be indigestible or to excite cutaneous irritation to be avoided, but all diet having a tendency to induce depraved nutrition is to be excluded; there is, therefore, to be instituted such a regulation of the quantity and quality of the food and drink taken, its mode of preparation, and time and method of consumption, as shall conduce to the restoration and maintenance of health. In this larger definition of diet all who see much of eczema in young persons (and old as well) must agree that it is an important factor in the proper management of the disease.

"Is eczema ever reflex—particularly in regard to the teeth?" Most assuredly, as far as relates to separate attacks or outbursts of the eruption, as may often be witnessed on each accession of a tooth in those subject to the same. But as to causing the disease, it is impossible that the physiological process of extrusion of the teeth can have any real effect in inducing the skin to take on true eczematous action when previously healthy.

"Outline of treatment." Only the briefest suggestions are possible within the limits of this article. The measures employed must vary very greatly according to the age of the patient, the susceptibility of the skin, the stage, degree, and extent of the eruption, and the physical condition of the patient; no two cases of eczema of any severity or duration can or should be treated exactly alike. Every little patient with any amount of eczema should be studied even more carefully than one with acute disease; for instinct and experience will often enable one to judge quickly in the latter case, whereas an obstinate case of eczema will often test the very best powers and acumen of the physician to discover and reach the element at fault in the case.

While eczema in children, as well as

adults, is often dependent upon faulty metabolism and disordered action of some of the emunctory organs, it must ever be remembered that it is a disease of lowered vitality. While remedies and measures are taken to promote excretion and assist assimilation, the tonic idea should pervade all treatment. On the other hand, too stimulating measures, dietetic or medicinal, may fail of action or even do harm when used too early or pushed too vigorously.

Mild laxatives are of great advantage at the beginning and during treatment; also remedies which promote the action of the kidneys, both as to solid and liquid ingredients.

While arsenic sometimes seems to have a wonderfully controlling action over eczema in young children when pushed to full dosage, in many instances it fails; and practically arsenic does not form a large element in treatment by those who have most experience with the disease.

Local measures must vary so greatly according to the stage and condition of the eruption, and also with the peculiarities of individual skins, that it is impossible to give briefly any indications as to their use. It may be stated, however, that the error most commonly committed is on the side of too strong and irritating applications. It should always be remembered that the eczematous skin is itself in an irritable condition, with Nature seeking to give relief to the irritation by an exudation from the congested blood-vessels and cells; further, that this erethistic condition is apt to be continually aggravated by the efforts of the patient to get relief by scratching. This scratching or rubbing attracts more blood to the part, and by laceration injures the deeper layers of the skin, which should be protected by an external, horny layer, which is more or less wanting.

Protection and soothing is therefore what the excited skin wants, and yet what is often very difficult to secure. The complaints or evidences of the itching will often cause the physician to use stronger and stronger applications, hoping to control it, and they will only too often prove more and more irritant to the delicate and excited cells, and really aggravate the inflammation and itching instead of subduing it. The reason of the well known popularity of the oxide of zinc ointment is because of its bland and non-irritating character, when well prepared, forming a protective coating over the inflamed part; subnitrate of bismuth acts in the same manner, and is rather more astringent.

#### PLEURITIS: ITS DIAGNOSIS AND TREATMENT.

PAGE of New York in the *Medical News* of February 13, 1897, contributes an interesting and practical paper on this subject. After considering the etiology and diagnosis he states that the treatment of acute pleurisy with sero-fibrinous effusion is generally directed first to the pain in the side. How are we to afford relief? Perhaps the simplest way would be to administer an opiate; in fact, if the pain is very severe, this will have to be done. The hypodermic injection of a moderate dose of morphine, to be repeated if necessary at proper intervals for the first day or two, may be all that is necessary, since it is only during the first few days that pain is an urgent symptom. In many cases morphine is not required. Dry cups have been highly recommended, but in my experience they are of little service and cause much annoyance to the patient. In case opium is not required, or even in conjunction with it, the question lies between hot and cold applications. Of these the writer does not hesitate to recommend the hot-water bag in preference to ice; it affords greater and more speedy relief than ice, and to the patient is much more comfortable. Hot applications, with or without opium, therefore appear to be the best remedies for the pain in the side.

The temperature in pleurisy rarely goes so high as to require interference, but should it be thought advisable to reduce it a moderate dose of acetanilid or ammonol—say three grains—can be given at noon and repeated at intervals of three hours until bedtime. This is a much better plan than administering quinine, unless a positive malarial condition is present, for with the exception of controlling temperature in malarial affections quinine is of little or no benefit, and often does harm by increasing head symptoms, such as delirium, insomnia, deafness, and the like.

Remedies to control the pulse can be given in pleurisy with far less danger of fatally depressing the heart than in pneumonia. For that reason veratrum viride, aconite, and similar medicines can be used not infrequently with great advantage, whereas in nearly all cases of croupous pneumonia they are, in the writer's opinion, out of the question.

As a rule, in ordinary favorable cases of acute pleurisy with effusion stimulants are not needed, but the physician would be guided in this as in other diseases by the character of the pulse, the patient's general condition,

and previous habits. In ordinary cases when stimulants are called for, as evidenced by the dry, brown tongue especially, a tablespoonful of whiskey or brandy in a little milk every three hours is sufficient; but among those addicted to intemperance a much larger quantity has to be administered. Digitalis, which is so highly recommended and often urgently needed in pneumonia, is seldom required in pleurisy, and the same may be said of nitroglycerin, carbonate of ammonia, and other so-called heart stimulants, the alcohol alone being quite sufficient.

Even to this day it is a common practise with the profession at large to apply blisters both in pneumonia and pleurisy. The writer disapproves of such practise, however common it may be, in the acute stages of these diseases. In acute pleurisy blisters would not only do no good during the first two weeks, say, but would do positive harm by interfering with the patient's comfort and also by increasing the rise of temperature. Should the case become tedious and the effusion remain stationary after the third week in spite of ordinary treatment, then blisters and other counter-irritations, as by means of the tincture of iodine, compound iodine ointment, and the like, might be tried, though even here aspiration would be better.

To cause the absorption of the effused liquid in the pleural sac in acute cases the best remedy he has tried is sodium salicylate. It may be given early in the disease, and in the same doses as in acute articular rheumatism. In fact, if we regard the pleural cavity as a large joint, there is no reason why it should not be subject to rheumatic inflammation and effusion, as the knee, for example, in acute rheumatic fever, and in some of these cases the sodium salicylate does certainly act speedily and effectually. On the other hand, the writer has observed but little benefit derived from the administration of iodide of potassium or such diuretics as acetate of potash with infusion of digitalis, diuretin, and so on. Such remedies do more harm by interfering with digestion and nutrition than any benefit to be derived from their use. But the sodium salicylate should be given with proper precaution. In some cases it so depresses the heart and causes such vertigo that its further use has to be discontinued at once. Also, if such symptoms do not arise so as to contraindicate its further use, it may just as well be discontinued after a few days or a week if such trial proves its action to be of no benefit.

An all-important question arises in the treatment of pleurisy with effusion: Shall we aspirate, and if so, at what stage of the disease, and at what point shall the needle be inserted?

In order to discuss this question properly let us refer again to three stages of acute pleurisy with effusion: (1) The dry stage, lasting only a few hours; (2) the stage of effusion, lasting usually from five to eight days; and (3) the stage of absorption, the whole duration being two or three weeks.

Of course, it is generally agreed that if the fluid has accumulated rapidly, as sometimes happens, and is excessive in amount, aspiration should be resorted to at once. Not only is life endangered by asphyxia from interfering with respiration, but if the heart be much compressed, as evidenced by its wide displacement and feeble and irregular beats, the patient may die very suddenly from heart failure. Under such conditions aspiration alone can save life, and it should not be delayed.

Generally, about half the fluid is withdrawn. That is usually sufficient to relieve the urgent distress. Moreover, the cough and pain in the chest caused by the expanding lung will now interfere greatly with further withdrawal of fluid, not to mention the danger of rupture of the lung. In a few days the fluid may have returned, and a second or even a third aspiration may become absolutely necessary. After this, in favorable cases, the exudation of fluid ceases, and what is left in the pleural cavity becomes rapidly absorbed, with complete recovery. But unless such urgent symptoms do present themselves—in other words, if the patient be doing well—are we to withdraw the fluid during the acute stage? Certainly not. The reason for it is obvious. There is a great tendency to the formation of adhesions in pleurisy under the best conditions. To draw off this fluid during the active stage of inflammation, as evidenced in part by the pain and temperature, would simply bring the inflamed surfaces together that had heretofore been kept apart by the effusion. Increased irritation with a more severe grade of inflammation would follow, and extending into the subserous connective tissue would convert a superficial into an interstitial exudation and result in a thickened pleura, if not extensive plastic adhesions. Such a termination would be extremely unfortunate, and due to unnecessary if not meddlesome interference. Both lungs would be damaged, the one from im-

perfect expansion due to such thickening of the pleura and extensive adhesions that hill-climbing or the use of the pneumatic cabinet would fail to break them up; the other from vicarious emphysema, in its effort to do compensatory work. It is to avoid these injuries to the pleuræ, with consequent permanent injury to the organs of respiration, that Potain and other eminent authors so earnestly recommend that in ordinarily favorable cases the operation be not resorted to before the second or third week, when all signs of active inflammation have subsided.

It has been recommended that the early withdrawal of the fluid might be practised while injecting sterilized air, thus converting acute pleurisy with effusion into pneumothorax; in other words, to substitute sterilized air for fluid as the medium for keeping the two serous inflamed layers apart. The air would become more rapidly and certainly absorbed, while at the same time remaining long enough to prevent the injury that would otherwise result from the immediate contact of the inflamed surfaces and sudden expansion of the lung. But as yet he has not learned that any practical result for good has been reached by such means. There is no danger whatever, in his opinion, that a sero-fibrinous effusion will be converted into a purulent one by the operation of aspiration if proper precautions, now so well-known to the profession, are observed.

But if drawing off the fluid is not good practise, allowing it to remain too long may be said to be equally bad. In this case the period of active inflammation is over, the stage of organizing has arrived, and if the lung be allowed to remain compressed and quiescent adhesions are almost certain to result.

#### THE TREATMENT OF PUERPERAL ECLAMPSIA.

In the London *Practitioner* for February, 1897, Gow gives a review of current midwifery literature. At the International Congress of Gynecology held in Geneva one of the subjects under discussion was the treatment of puerperal eclampsia. Until the pathology of eclampsia is better understood no rational treatment of the disease is possible, and it is more than probable that causes at work are not always the same. According to the statistics of Dr. N. Charles, of Liège, eclampsia occurs once in every one hundred and fifty-one deliveries, and is about four times as common in primiparæ as it is in

multiparæ. Among every four women who suffer from albuminuria during pregnancy one gets eclampsia. He teaches that it is most desirable to terminate delivery in all cases as speedily as possible when eclamptic convulsions set in, and with this object in view labor should be induced or accelerated as the case may be. In urgent cases the cervix must be dilated by the hand or by hydrostatic bags, and if this is impossible Cæsarean section should be performed.

Charpentier (Paris) on the other hand counsels that we should wait for labor to come on of itself, and that delivery should be allowed to take place spontaneously whenever possible, forced delivery being reserved for very exceptional cases. Venesection and the administration of chloral and chloroform are the remedies he chiefly relies on during the attack, and further suggests that diuresis may be favored by the subcutaneous injection of artificial serum.

Veit (Leyden) draws attention to the fact that many cases of eclampsia get well whatever the treatment may be, and states that there is no direct evidence that forced delivery under deep anesthesia improves the prognosis. He does not rely on any one method of treatment, but considers that the systematic use of large doses of morphine administered subcutaneously seems to give the best results. In addition he advises that the membranes should be ruptured, labor prudently accelerated, and delivery effected as soon as the soft parts are fully dilated.

Mangiagalli on the other hand advocates rapid evacuation of the uterus, and believes this to be the most important point in the treatment. If the case is a grave one the cervix should be forcibly dilated, and when this is impossible on account of an unusual degree of rigidity, Cæsarean section is justifiable, especially if the fetus is living.

Byers (Belfast) pointed out that the most probable hypothesis was that the convulsions were caused by a poison elaborated by the mother, or by the fetus, which accumulated in the blood owing to some failure in the normal processes of elimination. The treatment he advised was the administration of morphine subcutaneously, the woman being kept upon her side, and all liquids by the mouth being withheld. Hot-water or vapor baths, if obtainable, should be used. If labor has not begun the convulsions should be treated with morphine, but the uterus should not be excited, and no attempt should be made to bring on labor. In the first stage of

labor, when convulsions supervene, hydrostatic bags may be employed if the cervix is soft and dilatable; but if it is rigid no local measures should be used. In the second stage of labor he advises delivery with forceps after the patient has been anesthetized.

It will be seen that there is still no general agreement as to the best method of dealing with eclamptic convulsions, and Veit's remark that many cases get well whatever the treatment may be shows how difficult it is to judge dispassionately the merits and the demerits of the various plans adopted, and to determine to what extent they really play a part in bringing about the recovery of the patient. The most difficult question to decide is whether the first stage of labor should be hurried and delivery rapidly effected as advised by Charles, or whether it should be allowed to take its course as recommended by Charpentier and Byers. It is quite clear that unless the advocates of forced delivery can prove that their results are much better than those in which labor has been allowed to advance naturally, their methods will not find favor, as the risk of severe local injury from forced delivery is a real one. Further evidence is wanted on this point, and it is only by reviewing a large number of cases that the matter can be finally determined, because the severity and danger of death in different cases of eclampsia varies enormously. Some cases even where convulsions occur at short intervals get quite well, while others, after only a few or it may be a single convulsive attack, rapidly die, although the treatment adopted may be precisely the same in both instances. Until more certain knowledge has been obtained as to the precise pathology of these cases we cannot hope to advance very far towards a rational treatment.

#### ON THE PATHOLOGY AND TREATMENT OF CHILBLAINS.

In the London *Lancet* of January 30, 1897, WRIGHT, whose researches on the coagulability of the blood are so well known, tells us that he has investigated the condition of blood-coagulability in ten cases of chilblains. Two of these were cases of aggravated chilblains occurring in adult males; the blood-coagulation time of these patients was respectively nine minutes and nine and a quarter minutes. Four were cases of aggravated chilblains occurring in adult females; the blood-coagulation time of these cases was respectively thirteen minutes,

eleven minutes, eight and three-quarters minutes, and seven and a half minutes. Lastly, four of these ten cases were mild cases of chilblains occurring in schoolboys; the coagulation time of these cases was respectively eleven minutes, nine and a quarter minutes, seven and three-quarters minutes, and four and a half minutes. It is obvious, therefore, when we consider that the normal blood-coagulation time varies between three and four minutes, that all these cases of chilblains, with the exception of the last, were associated with a very notable defect of blood-coagulability. This fact stands in relation with certain other facts which obtrude themselves more directly upon the clinician's attention. These facts are: (a) the superior liability of children to chilblains; (b) the fact that chilblains are prone to occur in persons who give a history either of nose-bleeding or of urticaria; (c) the occurrence of chilblains in persons who are characterized by a lymphatic habit of body; (d) the not infrequent occurrence of chilblains in persons who are the subjects of malarial cachexia; and (e) the not infrequent occurrence of chilblains in hemophilic families. We will briefly consider each of these predisposing causes.

The notorious liability of children to chilblains is no doubt in part referable to the fact that the influence of cold makes itself felt more upon the relatively small extremities of the child than upon the relatively large extremities of the adult. Another probable factor in the etiology is the fact that the lime salts upon which the coagulability of the blood depends are in the growing child being continually removed from the blood in order that they may be deposited in the bones.

There is an obvious relation between the predisposition to epistaxis, the predisposition to urticaria, and the predisposition to chilblains, inasmuch as these predispositions have been shown to depend upon a defect of blood-coagulability. In two cases which have recently come under the writer's observation he has seen urticaria alternate with chilblains. Both these forms of serous hemorrhage were apparently brought on in susceptible patients by exposure to cold.

We shall understand the relation between the lymphatic constitution and a predisposition to chilblains if we consider, first, that the essence of the lymphatic constitution is to be found in a water-logging of the tissues which is dependent upon an excessive transudation

of lymph; secondly, that it will require only a very slight increase of transudation to convert such a water-logged condition of the tissues into perfectly definite hematomata such as we see in chilblains; and thirdly, that in all probability both chilblains and the water-logged condition of the tissues which we meet with in the lymphatic patient are ultimately referable to a defect of blood-coagulability.

The subjects of malarial cachexia are not infrequently also the subjects of chilblains. It is even possible, as the writer is assured by a medical officer who has experience of the truth of this fact in his own person, to suffer from chilblains on the West Coast of Africa after a severe attack of malarial fever. This liability of the malarious subject to chilblains is in absolute conformity with the fact that the blood of patients who are subjects of malarial cachexia is characterized by a defect of blood-coagulability which is dependent upon a great paucity of white blood-corpuscles, especially of polynuclear white blood-corpuscles.

The writer has pointed out in previous papers that the chilblains are of frequent occurrence in hemophilic families. This stands in connection with the fact that hemophilic blood is, as previously shown, characterized by an extreme defect of blood-coagulability which is dependent upon an extreme and hereditary paucity of white blood-corpuscles, and in particular upon a paucity of polynuclear white blood-corpuscles.

In view of the etiological facts thus disclosed the obvious indication for treatment is to take steps to augment the patient's blood-coagulability. In conformity with these indications the writer places his patients upon a regimen of calcium chloride (after duly cautioning them against lowering their blood-coagulability by the ingestion of sour fruits, alcohol, or excessive quantities of fluid). Of the eight cases which he details, six responded to this treatment with a marked increase of blood-coagulability. These were all cured as soon as a sufficient augmentation of coagulability had been achieved. In one of the remaining cases no good whatever resulted from the treatment; in this case, owing perhaps to the maladjustment of the dose of calcium chloride, no augmentation of coagulability was obtained. Finally, in one case only transient and uncertain amelioration was obtained from the treatment; and here, again, only a very transient augmentation of coagulability was obtained.

#### *THE TREATMENT OF DIPHTHERIA BY ANTITOXIN AT THE SOUTH DEPARTMENT OF THE BOSTON CITY HOSPITAL.*

In the *Journal of the Boston Society of Medical Sciences* for January, 1897, McCOLLOM makes the following report:

The South Department, devoted to the treatment of the three principal acute infectious diseases—namely, scarlet fever, diphtheria, and measles—was opened August 31, 1895. Previous to this time these diseases had been treated in the Boston City Hospital proper. It was found that the proximity of these wards to the hospital was a constant menace to the other patients, and also to the employees.

It has been claimed that hospitals for infectious diseases situated in a crowded locality become foci for the spread of disease. From the 1st of September, 1895, to the 1st of September, 1896, there were reported to the Board of Health 3989 cases of diphtheria. The hospital was taken as a center, and an analysis of the cases shows that within an eighth of a mile radius 11 cases occurred; one-quarter of a mile, 82 cases; half a mile, 238; three-quarters of a mile, 292; and a mile, 423; making a total of 1046. The remaining 2943 existed in other portions of the city—two, three, and in some instances five, miles away. The area of infection of scarlet fever is greater than that of diphtheria. The total number of cases of scarlet fever reported to the Board of Health for the year ending September, 1896, was 1043. Within an eighth of a mile from the hospital there were no cases; one-quarter of a mile, 68 cases; half a mile, 71 cases; three-quarters of a mile, 75 cases; within a mile, 72 cases; making a total of 286. The remaining 757 occurred more than a mile from the hospital.

The study and treatment of diphtheria has assumed a new phase since the introduction of antitoxin. The course of the disease has become shortened since it has been used. The most malignant types have been treated successfully. The type of the disease has not become milder in late years.

In Boston, from 1878 to 1894, the average death-rate was 30.7 per cent. In the Boston City Hospital, from 1891 to 1894, when antitoxin was not used, the percentage of mortality was 46. In the South Department for a period of thirteen months when antitoxin was used the percentage of mortality was 13.4. If the seventy patients who were admitted in a moribund condition were elimi-

nated it would bring the death rate down to 10.3 per cent.

In laryngeal cases antitoxin is of very great benefit.

At the Boston City Hospital, for the year ending January 31, 1895, there were 89 intubations and 74 deaths, giving a percentage of recoveries of 17. These cases did not have antitoxin. In the South Department for thirteen months ending October, 1896, there were 200 intubations, where antitoxin was administered, with a percentage of recoveries of 45.5.

An analysis of the 1972 cases treated shows that 1074 had membrane on each tonsil; 1030 of these were discharged well; 44 died. Of the remaining 898 cases 226 had membrane on one tonsil, three of whom died. In 202 cases the membrane covered each tonsil, the uvula, and the palate; 66 of these cases died. Membrane was found on each tonsil and the uvula in 195 cases; 34 of these patients died. Membrane was found on one tonsil, uvula, and palate in five instances; none of these patients died. There were 200 intubations with 107 deaths. There were 38 non-operative laryngeal cases in which there was membrane visible, two of whom died; 22 cases of non-operative laryngeal cases in which no membrane was discovered, no death occurring in this class of cases. There were ten cases of tracheotomy; of these, three died from extension of the membrane, four from shock, and the remaining three from bronchopneumonia. To sum up the 1972 cases, 34 per cent. had albuminuria; 12.3 per cent. had urticaria; and the percentage of cases in which it was necessary to give two doses of antitoxin was 8.9.

Of the 1702 non-laryngeal cases the culture was negative in 100 instances, or 5.8 per cent. In the laryngeal cases it is the exception that a positive culture is obtained so far as the presence of the bacilli of diphtheria is concerned, and yet in this class of cases 77 were positive of the 270.

It has been stated that albuminuria is caused by the use of antitoxin. Of the 1972 patients treated with antitoxin thirty-four per cent. had albuminuria, which proves that antitoxin does not increase the frequency of albuminuria, as this is not as large a percentage as occurs in cases not treated by antitoxin. In 173 cases the urine was examined before and after the administration of antitoxin. Of these 173 cases it was found that in ninety-nine instances albumen was absent both before and after the administration of antitoxin,

which was without doubt due to the fact that the healing serum was administered before the diphtheritic membrane had increased sufficiently to generate toxin enough to cause albuminuria. In thirty-three cases the albumen was about the same; in twenty-five the albumen was diminished, which seems a sufficient argument against the claim that antitoxin causes albuminuria. In sixteen cases the albumen was increased, but not to a sufficient extent to cause any special anxiety. As these were severe cases the conclusion that albuminuria was caused by the toxin of diphtheria and not by the healing serum is justifiable.

Eruptions of the skin of different varieties have been observed in 244 instances. These eruptions can be classified as urticaria, erythema, a papular eruption, an ecchymotic eruption which must be distinguished from the spots of ecchymosis occurring as an early symptom in severe attacks of diphtheria, a punctiform eruption resembling scarlet fever, and an eruption resembling that of measles.

The percentage of cases in which post-diphtheritic paralysis occurred is 5.8, which is not as large as occurs in cases not treated by antitoxin.

Experience shows that the best place for the injection is the upper part of the thorax, near the posterior axillary line.

From the study of these 1972 cases of diphtheria treated at the South Department the following conclusions are justifiable:

1. That antitoxin is a remedial agent of very great value in the treatment of diphtheria.
2. That the healing serum does not cause albuminuria.
3. That its use does not predispose to paralysis.
4. That in the laryngeal cases of diphtheria the benefit derived from its use is as great if not greater than in the non-laryngeal cases.
5. That the statement that has been made that antitoxin statistics, because based on mild attacks of the disease, are unreliable, is incorrect.

---

#### SOME POINTS IN THE TREATMENT OF INFANTILE DIARRHEA.

In the *Revue de Thérapeutique Médico-Chirurgicale* of December 15, 1896, LESAGE contributes an article upon this subject. He first points out that one of the most important things is the regulation of the diet. F

believes in an absolute sterilized milk diet, and the use of some mild alkaline water such as that of Vals or Vichy, to which may be added some white of egg to form albumin water.

He also insists that should the purgation be so active as to deplete the patient to a dangerous extent we should employ hypodermoclysis, or the subcutaneous injection of artificial serum or even of real serum. This latter recommendation is of course in line with that made by Cantani, who it will be remembered treated cases in one of the recent epidemics of cholera in Europe in this manner with extraordinarily good results, using as much as four to six quarts of saline solution for the adult. It is, however, to Luthon of Reims that credit for the introduction of hypodermoclysis in the treatment of cholera infantum is to be given, for in 1884 he reported the use of small doses of saline for this purpose. In 1888 Weiss recorded the treatment by injection of from one to two ounces in cases of cholera infantum with successful results; and Sahli, Wild, and Demieville have reported cases of very extraordinary recovery after as much as five ounces had been injected, as have also Houtinel, Thiecelin, and Marois. Other authorities might be quoted. The following solutions may be employed:

- ♢ Chloride of sodium, 100 grains;  
Distilled sterilized water, 1 quart.

Or Hayem's solution:

- ♢ Chloride of sodium, 75 grains;  
Sulphate of sodium, 150 grains;  
Distilled sterilized water, 1 quart.

This liquid is to be allowed to flow very slowly into the subcutaneous tissues of the belly-wall or back, divided up amongst three to six injections a day, generally given in the dose of thirty cubic centimeters each time.

In cases which are not so severe and where the purging is not so excessive, but where the child apparently is poisoned by toxins which have been absorbed, smaller doses amounting to five cubic centimeters are useful for the purpose of flushing the kidneys and acting as a stimulant. In other instances it may be well to use the formula of Cheron, as follows:

- ♢ Carbolic acid,  
Chloride of sodium,  
Phosphate of sodium, of each 15 grains;  
Distilled water, 3¼ ounces.

Very small doses of this solution may be used on account of the poisonous carbolic acid which it contains. In some cases if the patient is tuberculous these injections will

not only arrest a fall in temperature, but actually produce a fever, and for this reason the injection should not be used if there is any evidence of tubercular adenitis, as it has been found that this treatment may change a latent tuberculosis into an active one. The injection of blood serum possesses so many disadvantages that it hardly seems to us advisable, although it has been employed in a very considerable number of patients.

#### THE TREATMENT OF SYPHILIS BY INTRAMUSCULAR INJECTIONS OF BENZOATE OF MERCURY.

According to the *Revue de Thérapeutique Médico-Chirurgicale* of December 6, 1896, GALLOIS recently communicated to the Société de Thérapeutique his method of treating syphilis by intramuscular injections of benzoate of mercury. He condemns the employment of the insoluble preparations of mercury and advocates the use of the soluble salts, and endorses the formula of the Russian physician Stoukownenkoff, as follows:

- ♢ Benzoate of mercury, 4 grains;  
Chloride of sodium, 1 grain;  
Hydrochlorate of cocaine, 1 grain;  
Sterile distilled water, 1 ounce.

Thirty minims of this are to be injected deeply into the loose muscles of the back every day or two. The only pain following this slight operation is a sensation as if a bruise were present, which develops about two hours after the injection. The advantage of using the benzoate of mercury is that it is less painful than calomel and is rapidly absorbed.

#### THE USE OF SULPHATE OF SODIUM AS A HEMOSTATIC.

In the *Revue Médicale de la Suisse Romande* of January 20, 1897, REVERDIN contributes an interesting article upon this subject, experimental and otherwise, and concludes that small doses of sulphate of sodium (two grains every hour) are of great value in certain cases of capillary hemorrhage for the purpose of arresting the flow of blood. He has also found this method of treatment of value for the control of graver hemorrhages. His experiments upon animals seem to show, however, that the remedy is only of value if given by the stomach or injected into the veins. Under these circumstances it distinctly increases the coagulability of the blood. On the other hand, it is a noteworthy fact that its administration subcutaneously does not produce the same result.

*ANTISTREPTOCOCCIC SERUM IN SCARLET FEVER.*

RAPPOPORTE has employed antistreptococcic serum containing 0.5 of one-per-cent. carbolic acid solution in the treatment of scarlet fever in sixteen cases; four of these were not grave, and he thinks that the use of the serum prevented the aggravation of the infection. In two cases with symptoms of great infection the serum did not exercise much action; these two patients died. In the other twelve cases to whom the serum was given for the purpose of overcoming the symptoms no less than ten succumbed. He also found that the serum did not exercise any material influence over the ordinary course of the temperature, and concludes that its use is not satisfactory. It seems to be necessary that there should be marked streptococcic infection in addition to the infection of scarlet fever, for this treatment to be useful.—*Revue de Thérapeutique Médico-Chirurgicale*, Dec. 6, 1896.

*KELOID SCAR FOLLOWING THE APPLICATION OF IODINE.*

In *L'Abeille Médicale* of February 13, 1897, there is a case reported to the Society of Dermatology by THIBIERGE in which a young girl of fifteen had applied to the skin of the anterior portion of the thorax a considerable quantity of tincture of iodine, which was repeated once, the idea being to relieve an attack of bronchitis. Seven months afterwards a scar was present with distinct keloid manifestations.

*THE INDICATIONS FOR VENESECTION.*

ALBU has studied the influence of bleeding upon a series of pathological conditions and reviews the indications and contraindications for its employment. By bleeding we directly diminish the blood-pressure and the density of the blood, and modify materially its morphological elements. We thereby produce modifications in various parts of the system, and determine reactions in the presence of morbid processes. The chief indications for the employment of bleeding are two conditions: extreme arterial pressure with congestion of certain organs; and the accumulation in the blood of metabolic products or of foreign substances.

The first indication is met with in cases of apoplexy in vigorous subjects, with signs of plethora. It may also be met with in cases of epilepsy.

The second class of patients is met with in

those suffering with uremia. Bleeding is contraindicated in chronic interstitial nephritis with loss of compensation in the presence of feeble cardiac action and cachexia. It is an operation, however, which is to be recommended in the poisoning by the oxide of carbon and by illuminating gas and chlorate of potassium. In pneumonia its influence is not for good, unless the arterial pressure is very high or unless there is a tendency to pulmonary edema owing to feebleness resulting from myocarditis.

In young subjects bleeding is contraindicated should there be cardiac asthenia. In cardiac bronchitis, particularly that due to grippe, Albu thinks that free bleeding brings about excellent results. It also does good in cases of bronchitis with bronchiectasis. He has even seen it of advantage in pneumothorax and in disorders of compensation, and consecutive upon mitral stenosis. He believes that in myocarditis it must be used with prudence, and that it is contraindicated in chlorosis, although sometimes bleeding, by stimulating the blood-glands, may prove useful.—*Journal des Praticiens*, February, 1897.

*POISONING BY TRIONAL.*

A case is reported in *L'Abeille Médicale* of February 13, 1897, in which a man suffering from morphinomania and who was accustomed to employ morphine daily received habitually twenty grains of trional every night during a period of two months, or to speak more exactly, twenty-one drachms in twenty-six days. After one month the patient found it difficult to rise and was in a condition of continuous hebetude. He could with difficulty support himself, and the movements of his upper and lower extremities were exceedingly ataxic. There was tremor of the tongue, the feet, the hands, and the muscles of the face. The walk was slow and labored. In attempting to speak the syllables were transposed, or on attempting to write they were so disordered as to make the spelling very incorrect. There was profound psychic depression and general intellectual feebleness, with involuntary passage of urine.

*PANCREATIN IN THE DIARRHEA OF EXOPHTHALMIC GOITRE.*

In the *Journal des Praticiens* for February 6, 1897, LIEGEOIS reports his successful employment of full doses of pancreatin in the treatment of persons suffering from exophthalmic goitre.

*THE PICRIC ACID AND ARISTOL TREATMENT OF BURNS.*

Dr. Cookman writes upon the recent methods of treating burns in the *Hahnemannian Monthly* for March, 1897. As he states there is perhaps no subject in the realm of surgery that has been so extensively written upon and discussed as burns and their treatment. Medical literature since time immemorial has devoted countless pages to this topic, and each current magazine seems to bring forward some new drug or plan of treatment that will produce rapid and painless healing of this injury. Yet burns will be burns, and still continue to pursue the uneven tenor of their way, producing ugly contracting scars and taxing to the utmost the skill and patience of the painstaking surgeon.

The two methods of treatment advocated in this brief paper, although comparatively new in this country, have been tried and their efficiency thoroughly proven in England and on the Continent. Powers of London and Thiery of Paris report a long series of cases successfully treated with picric acid; while Walton of Ghent and Von Kliegel of Vienna publish an equally extensive list of perfect recoveries under the aristol treatment.

Picric acid and aristol belong to that group of remedies which have recently been prepared by synthetical methods and introduced into therapeutics. The former, as is well known, is a product resulting from the action of nitric upon carbolic acid. It consists of fine yellow scales, soluble in water or alcohol, to both of which it gives a brilliant yellow color. Its use in medicine has been a limited one, while in commerce and the manufactures it has been extensively employed as a dye. As a local application for burns it is best used in the strength of one and a half drachms dissolved in three ounces of alcohol, and then diluted with two pints of distilled water. This makes the so-called saturated solution of picric acid.

The greatest advantages of picric acid in the treatment of burns are:

1. The severe pain which is so characteristic of these injuries is considerably lessened, this being doubtless due to the carbolic acid of which it is largely made up, and which is a well-known local anesthetic.

2. It limits the tendency to suppuration on account of its strong antiseptic properties and the power it possesses of coagulating albuminous discharges. When we remember that the antiseptic carbolic and the coagula-

ting nitric produce picric acid, these properties are readily understood.

3. Healing takes place rapidly under a scab, and the resulting scar is smooth and shows but little tendency to contract.

Picric acid is most indicated in superficial burns and scalds, with vesication of the skin, and should be applied as follows: After careful removal of all clothing from the burnt part, the wound should be cleansed as thoroughly as possible with the solution of the acid. If a syringe is used for this purpose the surgeon can avoid staining his hands. All blisters should be pricked and the serum allowed to escape, care being taken not to destroy the overlying epithelium. Sterilized gauze is then spread over the burned area and soaked with the lotion. A layer of absorbent cotton is put over the gauze and the dressing held in position by a bandage. This dressing may be left in place three or four days, and then gently removed by thoroughly moistening it with the picric solution, for it will be found to adhere closely to the skin. Subsequent dressings are similarly applied, and after three or four, according to the degree of burn, healing will be complete.

A word of caution is necessary. Picric acid is poison, fifteen grains being considered a lethal dose. We must therefore watch over patients for toxic symptoms. These are a general yellow color of the skin and conjunctiva, orange-colored urine, sexual excitement, mental lassitude, and gastric disturbances.

Aristol is a combination of iodine, iodide of potash, and thymol. It is a light red, extremely fine powder, insoluble in water and glycerin, slightly soluble in alcohol, and readily dissolved in ether, collodion, and the fixed oils. As a cicatrizant it probably has not the toxic and irritating character of the latter, is practically odorless, and probably has some anesthetic properties. When applied to a wound it produces at first a slight burning, followed by a diminution of the painful sensations. Granulations spring up, healthy, vigorous, and vascular. Cicatrization takes place rapidly from the edges of the wound, and the scar seems to be less abundant in fibrous tissue, thus decreasing the liability to contraction.

Aristol may be used in all varieties of burns, from a simple erythema of the skin to a complete charring and destruction of the tissues. In the superficial form it is best used as a powder, while in the deeper burns the following ointment is to be preferred: Aristol,

one part; olive oil, two parts; dissolve and add vaselin, eight parts.

Strict asepsis of the wound, however, is the first essential to success. After pricking all the blebs and permitting the serum to exude, the burn should be well irrigated with a weak solution of boracic or carbolic acid, and its surroundings scrubbed with soap and water. Then with sterilized absorbent cotton the surface should be gently dried, and the aristol applied, either as a powder or an ointment. If the latter is used, the wounded edges are first dusted with the powder, and then sterilized gauze on which the ointment has been thickly spread is applied. The dressing is completed with another layer of gauze, absorbent cotton, and a bandage. After three days this should be removed, the wound and adjacent parts aseptically as before, and the same dressing reapplied. By careful treatment in this manner very extensive burns will rapidly cicatrize.

Although Cookman has described these two methods as separate and distinct, they may be combined.

---

#### AN OINTMENT FOR CHILBLAINS.

- ℞ Camphor, 20 grains;
- Balsam of Peru, 7 grains;
- Oil of almonds, 2 drachms;
- Lanolin, 6 drachms;
- Rose water, 6 drachms.

—*Journal des Praticiens*, Feb. 13, 1897.

---

#### AN OINTMENT FOR ECZEMA.

- ℞ Oxide of zinc, 1 drachm;
- Talc, 1 drachm;
- Olive oil,  $\frac{1}{4}$  ounce;
- Lime water,  $\frac{1}{2}$  ounce;
- Lanolin,  $2\frac{1}{4}$  drachms;
- Tincture of benzoin, 10 minims.

—*Journal des Praticiens*, Feb. 13, 1897.

---

#### THE TREATMENT OF ECZEMA.

In *La Médecine Moderne* for February 17, 1897, BESNIER writes a long paper upon this subject in which he points out that it is indispensable in these cases to prescribe a particular diet and a regular method of life, if encouraging results are to be obtained in the treatment of severe cases. Care should also be taken that all internal and external causes for tracheal irritation are removed as far as possible, and the urine should always be carefully examined to see that there is no renal cause for the difficulty, as evidenced by albuminuria, phosphaturia, oxyluria, glycosuria, or polyuria, occurring in the course of such

diathetic conditions as lithemia, gout, and diabetes. In regard to the methods of life Besnier points out that the patient should be as much as possible in the open air, must eat regularly of easily digested foods, the proteid constituents of which should be present in comparatively small amounts, and that fresh vegetables are useful, such as the various salads, cresses, and similar substances. Should the eczema be present in the new-born great care should be paid to the regularity of nursing and the clothes, particularly the diapers; and as healthy surroundings as possible should be provided.

Purgatives have been much abused by the physicians of earlier times in the treatment of eczema because they have been given in excessive quantities, but their moderate use should constipation be present is an absolute necessity. At first calomel may be given in small doses, or some of the neutral salines or castor oil or the preparations of senna. As diuretics it is well to employ some of the alkaline mineral waters, and to use to a great extent a milk diet. Belladonna is sometimes useful in cases of eczema in which there is a profuse sero-fibrinous exudate. Under these circumstances two to ten drops of tincture of belladonna may be taken quite frequently, or in its stead small doses of atropine may be given. If there is a contraindication to these drugs we may employ such remedies as tannin, agaracin, and phosphate of sodium. In persons who have a distinctly malarial history quinine is to be employed both for its specific and general tonic effect, and antipyrin, colchicum, and digitalis may also be used, particularly if there is a gouty tendency or feebleness of the circulation. Strychnine is useful if there is marked circulatory feebleness. In the eczema of the young, which is often dependent upon anemia in lymphatic persons, the administration of iron is often exceedingly advisable; in other cases it is better to give cod-liver oil or the iodide of iron; or in some cases if there is a tendency to arterio-sclerosis we may administer iodide of potassium with good results. If there is hereditary syphilis as an underlying cause of infantile eczema the iodide of potassium in moderate doses may be useful.

---

#### TREATMENT OF VOMITING BY MENTHOL.

The *Journal des Praticiens* for January 9, 1897, recommends the following treatment in incoercible vomiting:

- ℞ Menthol, 2 grains;  
Hydrochlorate of cocaine, 4 grains;  
Alcohol, 2 ounces;  
Syrup, 1 ounce.

A small teaspoonful every half hour until several doses are taken.

The following may also be used in case of the vomiting of tuberculosis:

- ℞ Menthol, 4 grains;  
Syrup, 5 ounces.

Shake well before using and give two to three teaspoonfuls at short intervals after each meal.

This treatment is an excellent one to follow the use of chloroform-water or ice.

According to Ferrand in some cases of spasmodic vomiting it is useful to apply the following solution to the pharyngeal wall by means of a cotton compress:

- ℞ Bromide of potassium, 75 grains;  
Glycerin, 2 ounces.

Such an application should be made after each meal to diminish the sensibility of the pharynx.

#### THE TREATMENT OF CANCER OF THE STOMACH,

In the *Journal des Praticiens* for January 9, 1897, is an article quoting ROBIN in regard to this subject. One of the most important points in the treatment of this disease in his opinion is the regulation of the diet and a diminution or absolute denial of albuminous food, with measures devoted to the prevention of fermentation of vegetable substances. The patient should also drink only in small quantities, and in those cases where there is hematemesis associated with a cancer, or obstinate vomiting, an absolute milk diet is necessary. The treatment from a medicinal point of view may be divided into the anti-cancerous and symptomatic.

The first can be met by three medications: first, condurango prepared in the following manner:

- ℞ Condurango bark,  $\frac{1}{2}$  ounce;  
Water, 12 ounces.

Macerate for twelve hours and then reduce to six ounces by boiling. A dessertspoonful of this may be given three or four times a day.

The second remedy of value is the chlorate of sodium, which is, however, distinctly contraindicated if there is albuminuria.

The following prescription may be used:

- ℞ Chlorate of sodium, 2 drachms;  
Distilled water, 3 ounces.

A small teaspoonful in the morning.

Third, aristol in pills containing one to two grains, and given three or four a day.

The symptomatic medication is as follows:

For improving the appetite small doses of strychnine and some good wine, and ten minutes before the meal the following in a cachet:

- ℞ Chloride of ammonium, 3 grains;  
Bicarbonate of sodium, 5 grains;  
Dover's powder, 2 grains.

With the object of favoring digestion, hydrochloric acid may be used to compensate for the absence of hydrochloric acid found in this disease. The following cachet may also be given:

- ℞ Pepsin, 8 grains;  
Extract of malt, 2 grains;  
Pancreatin, 2 grains.

For the purpose of diminishing fermentation sublimed sulphur in the dose of three grains, or iodide of sulphur in two-per-cent. strength given in the dose of five to ten grains in cachet after each meal. For the mitigating of vomiting we may have to use opiates, chloroform water, or cocaine, given five minutes after the repast. In other instances the following may be used:

- ℞ Picrotoxin, 1 grain;  
Hydrochlorate of morphine, 1 grain;  
Sulphate of atropine, 1-5 grain;  
Cherry laurel water, 2½ drachms.

Five to eight drops at a dose.

To combat hemorrhage ergotin is a most useful drug. For small hemorrhages the following may be given:

- ℞ Tannic acid, 10 grains;  
Powdered opium, 3 grains (this is a very large dose.—ED.);  
Sugar, 15 grains.

Make into six cachets, all of which may be taken in hourly doses.

For the relief of pain an ointment may be applied to the abdominal wall composed of extract of belladonna, extract of opium, and extract of hyoscyamus; and a plaster made with diachylon plaster, with one part each of these drugs to ten parts of the diachylon and two parts of the acetate of ammonium.

Internally the following may be given:

- ℞ Bromide of potassium, 1½ drachms;  
Hydrochlorate of morphine, 1 grain;  
Cherry laurel water, 2¼ drachms;  
Ether, 2 drachms;  
Syrup, 6 drachms;  
Distilled water, 4 ounces.

Dessertspoonful to teaspoonful of this may be given at a dose.

To overcome the pyrosis the following may be used:

- ℞ Calcined magnesia, 10 grains;  
Powdered opium,  $\frac{1}{4}$  grain;  
Subnitrate of bismuth, 4 grains;  
Bicarbonate of sodium, 10 grains.

In addition to these methods of treatment we must overcome the tendency to diarrhea or constipation as these conditions arise, and prescribe as healthy a life as it is possible for the patient to follow.

#### POWDER FOR CORYZA.

- ℞ Subnitrate of bismuth, 1 drachm;  
Powdered camphor, 6 grains;  
Finely powdered boric acid, 3 grains;  
Hydrochlorate of morphine,  $\frac{1}{4}$  grain;  
Hydrochlorate of cocaine,  $\frac{1}{4}$  grain;  
Powdered benzoïn, 15 grains.

This to be snuffed up the nose.

Or the following prescription may be used internally:

- ℞ Extract of hyoscyamus, 10 grains;  
Iodide of potassium, 50 grains;  
Bicarbonate of potassium, 2 drachms;  
Extract of liquorice, 1 drachm;  
Anise water, 3 $\frac{1}{4}$  ounces.

A dessertspoonful every four hours.

— *Journal des Praticiens*, Feb. 13, 1897.

#### THE THERAPEUTIC EMPLOYMENT OF DIGITOXIN CRYSTALS (MERCK).

There have been many attempts to produce the active principle of the *Folia Digitalis*, but no alkaloid has been produced which combined the therapeutically active principle of the drug in a form which was devoid of its disagreeable after-effects and yet was capable of being administered in accurate doses. V. STARCK (*Munch. Med. Woch.*, Jan. 26, 1897) reports a series of fourteen cases in which he has employed the drug within the last six months, achieving a success equal to that reported by Aubel, Masius, Wentzel, and Unverricht.

He employed the drug in the form of pastels containing about  $\frac{1}{16}$  of a grain as supplied by the manufacturers. The fourteen cases comprised ten cases of valvular failure, two of myocarditis, one of fatty heart, and one of arterio-sclerosis with passive congestion of the kidney. The tablets were well borne in all cases, and there were no symptoms of irritation, at least none sufficiently marked to make any other mode of administration necessary.

In the case of fatty degeneration the digitoxin had no effect. In one of the cases of myocarditis the effect was evanescent, while in a second after repeated attempts it produced good results where all other means had failed. In cases of valvular insufficiency

the action began four or five hours after administration. In the case of arterio-sclerosis with passive congestion of the kidneys the result was better, especially as regards the diuresis, than with any other infusion of digitalis. In one case of mitral stenosis, after eight doses had been ingested in three days, marked symptoms of digitalis intoxication were shown, the pulse falling to forty-six beats per minute. By the use of camphor injections the patient soon rallied, recovering completely in four days, was enabled to leave his bed, and remained well for three months afterwards.

The average dose was two tablets of  $\frac{1}{16}$  grain daily, the ingestion of ten doses generally sufficing; in only one case were twenty doses taken in succession.

Toxic effects followed after the eighth dose in one case.

#### IS THE INJECTION OF AIR IN HYPODERMIC MEDICATION A SOURCE OF DANGER?

In the *Journal of the American Medical Association* for February 27, 1897, McCCLINTOCK writes on this interesting theme. He says that in concluding a paper on "The Cause of Sudden Death After Antitoxin," Seibert and Schwyzer (American Pediatric Society, May 24, 1896) say: "We here express our firm opinion that the sudden deaths reported after antitoxin injections were caused by injected air and not by antidiphtheritic serum." He believes that this conclusion is without any justification whatever. It has been shown over and over again that relatively large quantities of air could be injected directly into the circulation in the lower animals without serious consequences. Senn, Hare, Adamkiewicz, and others have reported experiments in this line, with the conclusion that the danger from air-injection is small indeed.

Nevertheless it is believed by most practitioners that the accidental injection of even a small bubble of air may be followed by very severe consequences. Many of the older books teach this. The experiments and conclusions of Drs. Seibert and Schwyzer have been widely quoted and doubtless will add to the dread that many physicians have of hypodermic medication. As said before, he believes that their conclusions are wholly wrong.

The following experiments and the results agree substantially with those of Senn and

Hare. In the production of antidiphtheritic serum it occasionally happens that a horse is paralyzed from the injection of the diphtheria toxin. In such a case it is customary to kill the animal with chloroform. Recently McClintock had two horses so far paralyzed that they were unable to get on their feet. They were ordered chloroformed, but his assistants having read of the conclusions of Drs. Seibert and Schwyzer asked permission to try the effects of air injection. Horse No. 1, 20 Cc. air injected into the jugular, no effect; after five minutes 20 Cc., no effect; after five minutes 40 Cc., no effect; after five minutes 80 Cc., no effect; after five minutes 160 Cc., labored breathing. Horse No. 2, 320 Cc., into jugular; after one minute quickened respiration, spasmodic contractions of muscles; after four minutes, hiccoughs lasting ten minutes; fifteen minutes, uneasy but respiration slower, an occasional hiccough; two hours later no apparent effect. Several hours later this horse was given 600 Cc. air in the jugular; after one minute, struggling, spasmodic respiration. It acted as if choking, profuse sweating, temperature fell 0.4 degree; after ten minutes, symptoms all gone. Fifteen minutes later 1200 Cc. air injected; quiet, almost stops breathing; breathing stops ten seconds, then continues normal after a few minutes; after waiting twenty-five minutes and no symptoms appearing, the animal was chloroformed.

Dog, weighing about twenty pounds. The jugular was laid bare, and with a 20 Cc. syringe, sixteen syringefuls (320 Cc.) were one after the other injected. One minute after the injections began, quickened and labored breathing set in; in fact the symptoms were practically the same as in the horse, viz., dyspnea. A few minutes after the injections were stopped the animal recovered and normal breathing was reestablished. After an hour the injections were repeated with practically the same results.

Rooster, a small bubble of air injected; no apparent effect; then 1 Cc., the bird became somewhat dyspneic, acted just as a chicken that has run some distance, gasped for air, soon recovered entirely.

Rabbit, injected with 20 Cc. air, decided action at once; quickened respiration, spasmodic contraction of muscles, etc. After two minutes respiration became less frequent and gradually stopped; three and three-fourths minutes, dead.

Guinea-pig, injected with small bubble of air, no effect; after three minutes 1 Cc.,

quickened respiration, etc., but animal recovered entirely.

These experiments were repeated on different animals with similar results.

In observing these animals one is struck by the similarity of the phenomena to those of dyspnea, and indeed they are dyspneic. The air entering the heart and remaining there as an air embolus, as some would say, stops the circulation; or it passes into the heart and forms air emboli in the branches of the pulmonary portion of lung supplied by that particular vessel, and the animal becomes dyspneic. It is easy to see that if enough air is injected the circulation in the lungs may be so nearly stopped as to cause death, but one or several bubbles of air would merely temporarily close a few of the branches of the pulmonary artery. This air would be absorbed by the blood in a very short time, especially as it is in contact with venous blood and under arterial pressure.

The prevalent idea that if the ventricle is once distended with air it cannot empty itself, owing to the fact that the air is perfectly elastic and during the contraction merely becomes smaller in bulk, without forcing open the valves and escaping, he does not believe is justified. While the air is perfectly elastic and its volume would decrease with the increasing contraction of the ventricle, so inversely its pressure would increase, and as the ventricle practically obliterates its cavity at the close of the contraction, it seems to the writer that the pressure must open the aortic valves and force the air on.

The rabbit was killed in the above experiments with twenty cubic centimeters of air, but a corresponding amount for a forty-pound child would be 400 cubic centimeters, or far more than enough to occlude all the branches of the pulmonary artery.

As for ordinary hypodermic medication, or serum administration, the writer believes the danger from air injection is absolutely *nil*. In using the Koch syringe for giving small measured quantities of serum, toxins, etc., it is customary, in order to be sure that the entire amount of fluid is injected, to allow one or more small bubbles of air to escape from the needle. During the past six years he has made literally many thousands of such injections into rabbits, guinea pigs, rats, and mice, and he has yet to see any harm come from it.

Similar views to these have been expressed editorially in the GAZETTE within the last year.

*SERUM THERAPY IN SYPHILIS.*

In the *Boston Medical and Surgical Journal* for March 4, 1897, is an editorial dealing with this important practical subject. It shows that the serum treatment of syphilis has been employed hitherto in the three following ways: (1) Injection of the serum of healthy animals: dogs (Richet, Hericourt, Feulard); sheep and calves (Tomassoli, Kollmann, Mozza, Istomanow). (2) Injection of human serum from patients in the secondary and gumous stage (Pellizzari, Wjewiorowski); and from children with hereditary syphilis (Bonaduce). (3) Injections with serum from animals which had been previously inoculated with syphilis by means of (a) injections of the serum of patients with primary syphilis, or at the acme of secondary manifestations; (b) inoculations of primary syphilitic ulcers, and moist papules, as well as injection of serum of patients with the full development of secondary manifestations. No positive good results have thus far been proved to have followed the serum therapy.

Nevertheless, the great success of the serum therapy in diphtheria, and the attempts to produce a serum for the cure of erysipelas, pneumonia, cholera, etc., have encouraged students to continue their investigations of a serum therapy for syphilis. It has been shown in the case of diphtheria that the blood-serum of animals which possess a natural immunity from diphtheria has no therapeutic effect. In order to obtain an antidiphtheritic serum it is necessary that the animals be in a certain measure receptive to the inoculation. Tarnowsky believes that horses are more or less receptive to syphilis, as in some foals inoculated by him with syphilitic products nodular interstitial lesions were found in the liver, spleen, kidneys, and lymph glands, which showed microscopically a great similarity to those of syphilis. If, therefore, these animals are in some degree receptive to syphilis, a serum obtained from them when rendered immune by repeated inoculations would be completely analogous to an antidiphtheritic serum.

On this assumption three young horses were treated by successive inoculations with the products of syphilis, and the serum obtained from their blood was injected experimentally into six syphilitics who had had no previous treatment. The result of these experiments showed that the injection of serum from syphilized horses had no favorable influence on the course of syphilis, not only in the earlier but also in the later stages of the

disease, and that it was not to be recommended as a method of treatment. It was found, moreover, that the injections exercised an unfavorable influence on the general condition of the patients, causing a rise in temperature, albuminuria, outbreaks of purpura, and a loss of weight.

The question of serum therapy as a cure for syphilis may, however, be approached from a different standpoint. In case, as was conjectured by Behring, the efficiency of antitoxin consists, not in a destruction or neutralization of the toxins, but in an increase of the capacity of the system for resistance, it is conceivable that in the treatment of syphilis by mercurials we do not directly disinfect the system, but increase its power of resistance. On this supposition it is possible that the serum of animals which are in some measure susceptible to syphilis, and whose immunity has been increased by saturation with mercury, may be effective in the treatment of syphilis in man. Experiments on these lines have been already undertaken by Tarnowsky.

In 1891 Boeck treated a dozen cases of recent so-called secondary syphilis by means of injections of syphilitic serum obtained from the fluid of a hydrocele, in a syphilitic subject in the secondary stage. The results were not very striking. Of four patients treated in private practice only one had a slight recurrence of syphilitic symptoms. No news was obtained of the hospital patients.

During the last year somewhat similar experiments were made on seven patients from private practice. The serum was taken from a man who had acquired syphilis six years before and was then suffering from epididymitis and hydrocele. In the first six cases the treatment was begun before the outbreak of secondary symptoms, in the last case after the appearance of the exanthem. The injections were made into the skin of the back. The results of these experiments were that the primary symptoms disappeared more quickly under serum injections than under expectant treatment. Sometimes the effect was quite striking. The glandular affection of the primary period was also influenced. When the injections were made before the appearance of secondary lesions the latter were delayed and attenuated, so that the exanthemata were barely visible, and there were few appearances on the mucous membrane. Boeck found that the injections were more effective the earlier they were begun, and that this tertiary serum was far more

effective than that of the secondary period. He is forced to admit, however, that the serum injections do not have nearly so quick and decisive an effect on the symptoms of the early period as the ordinary specifics, mercury and iodine. In six cases of those treated by the injection of serum the secondary period lasted on an average four months and twelve days, and all secondary manifestations had disappeared on an average six months and three weeks after the date of infection. These cases were followed for many months; and Boeck is satisfied that the secondary period was surely at an end. The question now arises, How does this result compare with that attained by ordinary specific treatment? Do not secondary appearances last longer on the average under the latter method?

#### CANCER OF THE RECTUM.

Writing on Cancer of the Rectum TUTTLE (*Journal of the American Medical Association*, April 3, 1897) in conclusion states that:

1. Cancer of the rectum can be cured in over ten per cent. of the cases.
2. The mortality from the radical operation, though still considerable, is not alarming, and is decreasing with every year's experience.
3. The radical operation prolongs life on the average over 100 per cent.
4. As a palliative measure, excision is far more successful and beneficent than any other measure.
5. The sequences, though numerous, are not at all intolerable and should weigh little in our consideration when it is a question of so serious a disorder as cancer of the rectum.

And thus we answer the question, "What has modern surgery done for cancer of the rectum?" It has cured it, conquered all its disgusting features and relieved its pain, doubled and more the lease of life, and at comparatively small risk has given to the hopeless hope, not timorous and vague, but well-founded, and which grows stronger and more confident every day they live without recurrence.

#### PREGNANCY AFTER HYSTEROPEXY.

GIBERT (*L'Obstetrique*, March 15, 1897) is of opinion that ventral fixation of the uterus entails no trouble should pregnancy occur, provided that the anterior and upper part of that organ be fixed to the abdominal walls. The common error of operators is to fix the top of the fundus at the level of the insertion

of the tubes, low down and close over the bladder. The cervix is thus brought upwards, lying unnaturally high and very far back. When pregnancy occurs it is only the posterior wall of the uterus that can develop. In one case, where the fundus was thus fixed the fetal head lay in a natural attitude, though the height of the cervix was awkward for the obstetrician. The shoulders, however, lay in a big pouch to the left, separated from the head by a kind of spur. This pouch was the left half of the back of the uterus, which had developed very irregularly. Turning was effected with difficulty; as the shoulders were delivered the uterus straightened itself, and it was found afterwards that it had broken away from its adhesions. The child was saved. When the front of the uterus is well opposed to the parietes the entire organ can develop during gestation, the cervix is not inconveniently placed at labor, and the anterior adhesion remains intact after delivery. Gibert describes a case in which this satisfactory result ensued. Involution was rapid, whilst in the first case the detached uterus apparently maintained its deformed condition.—*British Medical Journal*, April 17, 1897.

#### SUPRAVAGINAL AMPUTATION OF A PREGNANT MYOMATOUS UTERUS.

A. G. T. BECKING (*Weekblad van het Nederl. Tydschr. voor Geneesk.*, January 16, 1897) reports his third successful case of myomotomy during pregnancy. The patient was a woman aged 38, who had suffered in infancy from convulsions and hemiplegia, and had menstruated irregularly and scantily since her twelfth year. In 1894 she suffered from abdominal pain; and in the succeeding year she married, and thereafter menstruation became more regular. She became pregnant in May, 1896, and shortly thereafter began to suffer from pain in the abdomen and difficulty in urination. Hard masses could be felt in the abdomen, which were diagnosed as uterine fibroids. The abdomen was opened in August, and two subperitoneal fibroids with thick pedicles were discovered, along with several small and large interstitial ones. The whole mass of the uterus and fibroids was therefore removed supravaginally by Treub's method. The mother made a good recovery and left the hospital on the twenty-sixth day.—*British Medical Journal*, March 27, 1897.

## NON-LIGATION OF UMBILICAL CORD.

KELLAR (*Pacific Medical Journal*, January, 1897) advocates non-ligation of the cord; he has practised it in more than 2000 cases, and after careful observation of these and other cases summarizes as his views: (1) Ligation in man is unnecessary because (a) it is not required at birth of any other animal; (b) the imagined necessity to prevent hemorrhage does not exist; (c) to tie for cleanliness is superfluous; (d) it is unreasonable to consider such an imperfection as needs ligature exists. (2) Ligation is in many cases injurious, (a) because it may justly be considered the cause of secondary hemorrhage; (b) by interfering with desiccation, and thus preventing separation, it gives rise to ulceration, with not infrequent consequences of erysipelas, fungoid excrescence, etc.; (c) it causes inflammation of funicular vessels by keeping them distended with unnaturally retained blood, hindering their normal obliteration, and laying a foundation for phlebitis, jaundice, pyemia, etc.; (d) by preventing normal escape of blood and thus causing hyperemia and congestion of portal circulation, it may lay the foundation of numerous infantile affections apparently originating in congestion of these vessels. (3) Certainly in some, and probably in not a few, cases ligature has been directly fatal; (a) numerous fatal cases attributed to ligation have been recorded by the highest authorities; (b) it can be seen in the newborn that the ligature maintains the right ventricle in a state of distension, otherwise relieved by bleeding from the hypogastric arteries, and this prevents renewal of action if the heart has stopped, or hastens its stoppage if it is failing; (c) in many instances removal of the ligature has saved life when other remedies have failed.—*British Medical Journal*, April 17, 1897.

## SIX CASES OF STRANGULATED HERNIA IN INFANCY OR EARLY CHILDHOOD.

PAGET (*West London Medical Journal*, April, 1897) in a paper with this title reaches the following conclusions:

(1) In three cases the hernia seems to have become strangulated while the child was at rest, either in bed, or in its perambulator, or lying on its back.

(2) In two cases, though the bowel had not long been strangulated and was but slightly injured, yet the scrotum was already congested or inflamed.

(3) In three cases, after division of the

stricture, reduction of the bowel was certainly made easier by holding up the child's feet, so that only its head and shoulders rested on the table.

(4) In more than one case the operation was made difficult by the extreme thinness of the sac—a mere film of membrane—and by the absence of fluid from it.

(5) In most of the cases the bowels acted within a few hours of the operation, and in two of them there was slight diarrhea for a few days.

(6) The writer did not do a radical cure in these cases, being anxious not to prolong the operations, and thinking that the tissues, in such very young children, would heal firmly without it; but the relapse of the hernia in Case 3 and the breaking down of the wound in Case 4 seem to show clearly that in all these cases we ought to tie the sac and close the ring.

(7) The breaking down of the wound in this fourth case is somewhat hard to understand. A whole week had passed since the operation; the stitches had not been touched; the wound had been dressed that morning, and then looked firmly healed. In the evening it broke down along its whole length, its edges curling inward like the edges of a wound in the scrotum. He is having sections made of the skin over the inguinal canal in young children, to see if it contains unstripped muscular fibres like the tunica dartos; it is hard to see what else can have made the edges of the wound thus give way and turn inward.

(8) In the last case the hernia was certainly reduced when the child was admitted, for the bowels acted freely for ten days. The scrotum remained much thickened and inflamed, and thus the relapse of the hernia was not at once noticed.

Thus these six cases seem to show that there are some points of special interest in strangulated hernia in infants. It is not unlikely to occur while the infant is at rest, and in infants vomiting it is so common that a strangulated hernia may easily be overlooked, as happened in three fatal cases among those collected from various sources by Mr. Marsh. The scrotum may be congested or inflamed very early, even though the bowel be but slightly damaged. Especial care is necessary in the operation on account of the extreme thinness of the sac and the very small quantity of fluid in it. The return of the bowel after division of the stricture may be helped by lifting the child's feet. The bowels are

likely to act soon after the operation, and to be somewhat relaxed for a few days. In every case a radical cure should be made at the time of the operation, unless the child is so collapsed that it is dangerous to prolong the operation even for a few minutes.

#### CONGENITAL TRANSVERSE DIVISION OF THE GLANS PENIS.

HOFMOKL figures and describes (*Archiv. für Klin. Chir.*, liv, heft 1, 1897) a rare case of congenital transverse division of the glans penis into two parts, a dorsal larger and a lower smaller part. The urethra opened into the middle of the dividing furrow, and was surrounded by a frenulum which passed on to the upper part of the glans, while on the lower part was seen the orifice of a blindly ending duct about two millimeters long. The patient was a man sixty-eight years old who had been twice married and had eight children. He suffered from congenital phimosis, and it was during operation, when the prepuce was turned back, that the anomaly of the glans was for the first time revealed. Hofmohl is unable to find in embryology a clear explanation of the origin of this defect. —*British Medical Journal*, March 27, 1897.

#### GONORRHEA IN WOMEN FROM A MEDICO-LEGAL STANDPOINT.

NEISSER discusses this important question with especial reference to the importance of the diagnosis, which, he affirms, cannot be positively made without the aid of the microscope. A secretion may be present which bears an exact resemblance, microscopically, to gonorrheal pus, but contains no cocci, or in fact any bacteria whatever (*American Journal of the Medical Sciences*). Moreover, it is impossible to determine the time at which infection occurred, since its course differs so widely in different subjects. When the cervical canal is affected, but not the urethra, symptoms may be absent. The writer denies the truth of the statement that obscure acute gonorrheal infection in the female may cause a chronic discharge in the male; the gonococci always possess the same virulence, and when they come in contact with healthy mucous membrane produce an acute inflammation. This explains the violent gonorrheal attacks in newly married women whose husbands regard themselves as entirely cured, and also the similar acute infection of men after intercourse with women whose physi-

cians had discharged them as free from disease. In both instances the secretion is found to contain a few scattered cocci, which are found only after a long search. In the chronic cases the characteristic appearance of the gonococci within the cells is often wanting, and the culture test is frequently unsatisfactory. In short, the microscopical diagnosis is often exceedingly difficult. Still, this is the only one which should be admitted as positive in a court of law. Dr. Simon has recorded the following interesting case: A man aged 37 years was accused of having committed rape upon a little girl five years of age, and of having infected her with gonorrhea. An examination of the greenish pus which escaped from her vagina showed that it contained Neisser's cocci. The accused denied that he had had urethritis or any venereal trouble since an attack of clap fifteen years before, which had been promptly cured. Careful and repeated examinations of his urethra showed an entire absence of any abnormal secretion. A bacteriological examination of the urinary sediment demonstrated the presence of numerous epithelial cells containing bodies which somewhat resembled gonococci, but which, when subjected to staining by Gram's method, failed to respond to the ordinary test. Under these circumstances it was impossible for the expert to submit a positive opinion. Hence the inference that, when the question of the specific nature of an old urethral discharge is to be decided, too much reliance should not be placed on the bacteriological evidence. Even when cocci are demonstrated in the vaginal secretion, the origin of the infection, whether direct or accidental, may remain in doubt. —*Medical Record*, March 20, 1897.

#### VENTROFIXATION.

KUSTNER (*Volkman's Klin. Vorträge*, No. 171, December, 1896) has prepared a valuable statistical monograph on these proceedings, which are condemned by many and strongly advocated by others. Of ventral fixation of the uterus 1120 cases are recorded, 265 in multiparæ, 830 in parous women, and 25 in old subjects. In 637 the displaced uterus was found fixed by adhesions; only seven died, two deaths being from direct obstruction. In most cases the results were noted as "good," but in at least 44 the displacement recurred; 122 became pregnant after the operation; pregnancy and labor were normal in 74. Amongst bad results in pregnant cases were

fifteen abortions and premature labors, one tubal gestation, three crossbirths, and one retained placenta. In two Cæsarean section was found necessary, and in one of these cases it was performed by the operator who had fixed the uterus. Twice as many bad results in pregnancy were noted after Leopold's as after Olshausen's method of ventrofixation. Of vaginal fixations Kustner has collected 376 direct, and 410 where the vesico-uterine fold of peritoneum was opened. The patients were: nulliparæ, 87; parous, 502; elderly, 24. The majority, 514, were in cases where the uterus was not bound down by adhesions, the reverse of the proportion in the ventrofixation series. Three deaths occurred. In 72 patients the displacement of the uterus recurred soon after operation; in 92 functional uterine disturbances followed; out of 46 who became pregnant, 23 suffered no trouble, 13 aborted, 5 had bad labors, and in 5 the retroflexion was found to return in the puerperium. Of Alexander's operation 120 are collected: in nulliparæ 26, in parous subjects 79, no statement of 15. In as many as 100 the uterus was expressly stated to be free from adhesions, in only three was it noted as fixed, and in one of these three the adhesions were broken down as a preliminary operation (Schultze). Recurrence of the retroflexion occurred in one case during convalescence, in 12 later; in 27 the result was expressly stated as satisfactory, but many after-histories were defective; 27 became pregnant; of these details are wanting in two, whilst twenty had normal pregnancies, and five aborted. Kustner gives statistics of several other operations for retroflexion, but they are too limited to be of any practical value.—*British Medical Journal*, April 17, 1897.

#### PRACTICAL WRINKLES IN THROUGH-AND-THROUGH DRAINAGE.

The following is applicable in any part where a through-and-through drainage tube is to be used.

The procedures were suggested and are particularly effective in overcoming certain difficulties in the maintenance of drainage in an empyema.

The first has reference to keeping the tube patulous by removing collections of pus and cutting off the granulations which grow down into the fenestra of the tube. It consists of an ordinary drainage tube with the requisite number of fenestræ, through the full length of which (previous to insertion) a strong silk

ligature has been passed. This silk is of a length about four times that of the tube, and has fastened at about a tube's length from one end of it either a split shot, the size of the caliber of the tube, or a section of rubber tubing. If a section of tubing is used (and this is more satisfactory) it should be of pure gum and just large enough to pass through the tube with some friction. The tube is inserted in the wound in the usual way and both ends are held with safety pins inserted in such a manner as not to infringe on the lumen. The two ends of the silk are knotted to form an endless string with the knot on the outside. When the tube becomes occluded, it is first moved in the sinus to cut off the granulations, and then the drag is pulled through the tube and everything in the form of pus is completely removed.

The second refers to the secondary or horsehair drainage. This consists of a strand of horsehair of the required thickness which has, at the proper distance from each other, two silk threads tied tightly around the strand with one end of each cut short and the other left the length of the drain. The strand is then cut squarely off at each end, one-fourth of an inch beyond the knotted silk. Then the knot and end of the strand are covered with sealing-wax which is shaped into a round probe and with the silk cord protruding from the tip. To insert the horsehair, the silk is attached to the silk of the drag, and the probe end is brought up snugly into the end of the tube. Then, as the tube is removed, the drain follows without giving extra pain. In case there is no cord in the tube, the silk of the drain can be threaded through a curved needle and the needle passed through the wall of the tube from within out. Then the end of the drain can be drawn up into the tube as before. After the drain is in place the two silk cords can be knotted. This will be found especially advantageous with children and nervous people; one quick jerk will remove the tube and locate the drain.—*Medical Record*, March 20, 1897.

#### PECULIARITIES OF THE SURGICAL DISEASES AND INJURIES OF THE POSTERIOR REGION OF THE NECK.

SOUCHON in the *Journal of the American Medical Association* for April 17, 1897, concludes an exhaustive paper on the above topic as follows:

Congenital atrophy and hypertrophic malformation of the posterior region of the neck are rare. Congenital deviations are due to the congenital affections of the vertebræ and to torticollis.

Acquired or post-natal malformations, atrophic and hypertrophic deviations, are due to neuroses (torticollis, paralysis), to injuries, inflammations, gangrene, ulcers, fistulæ, tumors, operations, cicatrices.

Swellings of all kinds, due to the same causes, may be observed, but present nothing peculiar; the most common is the one produced by the chronic arthritis of the articulations between the occipital and the vertebræ themselves, and called the post-cervical or occipital arthritis or sub-occipital disease.

Burns and frost-bites are only particularly important here because of the cicatrices which may follow, causing disfigurement in an exposed part, and also possibly causing deviations of the head from retraction.

Contusions are more frequent than in front; they are particularly painful because the muscles contused are those which keep the head in balance; they are often accompanied by fracture of the spinous processes and laminæ; contusion and concussion of the spinal cord and even of the brain.

Punctured, non-penetrating wounds, *i.e.*, not penetrating the vertebral artery and the spinal cord, are simple wounds and seldom give rise to any trouble. However, should they be large punctured wounds and strike the deep cervical artery or the posterior jugular vein, they may give rise to serious hematoma. When this persists it should be aspirated or incised. When it pulsates it is a traumatic aneurism of the said artery and it should be treated as such. Punctured wounds of the vertebral artery may give rise to an aneurism also which must be treated as such, that is, by ligating above or below, or both, when possible, and then incised. Much hemorrhage must be expected from the untied end, and the surgeon must plug tight with aseptic sponge and make firm pressure with a bandage.

Punctured wounds of the spinal canal through the interlaminar spaces, when the head is flexed forcibly, or through a fracture of the laminæ, are serious only if they become infected. Incised wounds reaching the spinal cord itself are followed by paralysis of the parts below. If the wound is and remains uninfected the cicatrization by primary union may take place and the paralysis disappear; if not, it will be permanent. If between the

occipital and the atlas or the axis the oblong medulla is severed, death is instantaneous. Infanticide is often produced by a long needle or pin driven between the occiput and the vertebra. If the lesion is above the origin of the phrenic, death follows quickly by paralysis of the diaphragm. Incised wounds of muscles are usually due to saber cuts; they may reach the vertebræ when the head drops forward; the hemorrhage is great. Incised wounds of the vertebral artery give rise to profuse hemorrhage. The peculiarities of the treatment of these wounds is prompt attention to the vertebral, the impossibility of ligating both ends if it has been wounded high up, the suturing of the large muscles, the difficulty of keeping the head steady, and to secure drainage; a liquid glass bandage or a jury-mast apparatus will assist materially.

Wounds of the posterior region are said to be followed by sexual impotency when the membranes of the cord are involved; by paresis and wasting of the lower extremities; also of the testicle. Larrey contends that this may take place even when the cord is not affected. Contused or lacerated wounds present nothing particular.

Gunshot wounds are usually serious if they reach the membranes on the cord. When pressure symptoms are present, very extensive and deliberate dissections must be done to remove the ball, the fragments of broken lamellæ, or clots, or foreign bodies, which cause the pressure. Poisoned wounds, stings, bites, present no peculiarities. Foreign bodies causing pressure-symptoms on the cord must be removed at almost any cost.

Ruptures of the muscles of the nucha are reported in those who carry heavy loads on the head; the symptoms are those of other muscular ruptures.

Ruptures of the attachments of the rhomboid and of the elevator of the angle of the scapula have been seen in farm laborers. Sprains, dislocations, fractures of bone, belong to another chapter. Shock accompanying the injuries of the posterior region is usually great, being often complicated with concussion and confusion of the cord, of the cerebellum, or of the whole brain.

Neuroses are represented by the acute torticollis (posterior) of the trapezius. It is said to be even more frequent than the torticollis of the sterno-mastoid. When in the trapezius and complexus the head is inclined to the affected side, but the face is turned toward the opposite side; the head is slightly

thrown backward. There is no cord, no diffuse induration, no atrophy of the face; the pain is near the atlas and is increased by pressure; under anesthesia the head can be straightened. This torticollis may be confounded with occipital arthritis with inclination of the head. The treatment consists in applying a soluble glass bandage apparatus; it should be worn one year. When both the trapezius muscles are affected the head is thrown back. In cases of torticollis of the trapezius the sterno-mastoid is often also contracted, but it is a contraction of immobilization; the pain is along the trapezius and not along the sterno-mastoid. Very often the torticollis affects also simultaneously the deeper muscles, the splenius, the elevator muscles of the scapula, the rhomboid. The scalenes and the platysma are sometimes the site of torticollis. Chronic or permanent trapezius torticollis is rare.

Softening or induration present nothing of special interest.

Congestion of the posterior region presents nothing special. Acute inflammation of the skin is represented specially by large boils and carbuncles; they are comparatively very painful; they give great pain because the tissues are inextensible; sometimes they are followed by extensive sloughing, when the general health is low, specially if diabetes be present; they are also serious because the veins of the upper part of the region open into the sinuses of the dura mater. The circumscribed anthrax is not as grave and is usually amenable to ordinary treatment. Diffused anthrax extends continuously from the superior curve line of the occipital to the seventh cervical and from one ear to the other; nothing stops it, not even the largest or deepest incisions, until it has reached the above limits. It is as if a certain extent of tissue was infiltrated with microbes, or as when an artery is obliterated and gangrene continues until all the area of the artery is mortified (Tillaux). Extensive incisions are even hurtful until limitation has been established, on account of the shock of the operation. When limitation has taken place, then incisions or the curette assist in removing the mortified tissues. Acute cellulitis, extensive gangrene, post cervical abscess, or phlegmons, are sometimes observed here when the general health is low, specially if diabetes be present, and for the other reasons explained above. They are really adeno-cellulitis or phlegmons, because all inflammation here begins in the glands; they are usually due to

the disease of the skin and scalp; they may be superficial or deep. Deep abscesses usually cause great pain on account of the thickness of the skin; they give rise to but very little redness and edema; they have a tendency to flatten and spread because of the thickness of the skin; they are slow in becoming superficial for the same reason; the knife must penetrate deeply to reach them. Acute lymphadenitis, however, is itself rare; it is due to lesions of the scalp and skin. Chronic inflammations are represented specially by ache, by syphilitic eruptions, and by the well-known syphilitic adenitis of the suboccipital and mastoid regions; these lesions are so constant in syphilis that Ricord used to say that was the place to feel the pulse of syphilis.

Gangrene of the region is serious when extensive or deep, on account of the cicatrices and their consequences. Ulcers are rare and present no peculiarities. The same is true of fistulæ.

*Tumors of the posterior region of the neck.*

—Gaseous tumors are represented only by the extension of an emphysema.

*Liquid tumors.*—Liquid hematoma presents no peculiarity. Varix and angioma are very rare. Aneurisms of the vertebral artery are not rare in this region; they are usually traumatic and are often high up. The artery should be ligated above and below, if possible, or above or below whenever possible, and the sac incised and immediately plugged with aseptic sponges; if possible, the distal bleeding end should be ligated. In case a secondary hemorrhage should occur through the distal end and be uncontrollable by plugging, the ligation of the vertebral on the other side must be considered and weighed.

Lymphangiomata are rare here. Serous cysts and congenital cysts are sometimes median and sometimes lateral; they may reach as low down as the dorsal region and from the rachis to the acromion; they are usually met with in children born prematurely and presenting other malformations; they are sometimes transformed into lipoma; according to Lannelongue they are congenital cystic lymphangioma. Mucoid cysts and dermoids are rare and present no peculiarities. Bursal cysts or hygromata are sometimes met with over the spinous processes of the seventh cervical. Purulent cysts or chronic abscesses, idiopathic or symptomatic, or by congestion, are rare here.

*Solid Tumors.*—Comedones are not rare, neither is keloid. Clotted and solidified hem-

atomas present no peculiarities. Sebaceous and dermoid cysts are usually difficult to dissect because they are so intimately adherent to the surrounding tissues. Simple adenoma or lymphadenoma, adenoma of Hodgkin's disease, strumous and tuberculous adenoma, are comparatively rare. Adenomata syphilitica, *i.e.*, the chronic enlargements spoken of above, are very common and almost pathognomonic of syphilis. A case of gumma of the trapezius has been recorded. Adenoma due to glanders is most rare.

Lipoma is common. The circumscribed form is the most frequent; this region is a site of predilection; it sometimes sends fibrous processes to the vertebræ. A peculiar circumscribed form of lipoma is described in prostitutes over the point of junction of the neck and back of the curve seen there, and due, it is said, to the position they so often have to assume. Diffuse lipoma is sometimes limited to the region and sometimes a part of the diffuse kind of lipoma which occupies the whole circumference of the neck like a cravat; it is such in some cases that it is impossible to fix the limit of its margin, *i.e.*, to say where it ends and where the natural fat begins. Fibroma of the region sometimes also presents adhesions to the vertebræ. Cervico-dorsal fibromata are common (Guyon); myxema, myoma, neuroma, chondroma, osteoma, are rare. The same is true of encephaloid, melanotic, colloid pulsating sarcoma, epithelioma, carcinoma, scirrhus; and they present no peculiarities.

The surgical operations of the posterior region of the neck present no peculiarities.

#### DILATATION OF THE STOMACH.

LYMAN in a paper on this subject in the *Journal of the American Medical Association* for April 17, 1897, states that the recognition of well-marked dilatation of the stomach is not difficult. Congenital enlargement or normally low position of the stomach may be differentiated from morbid dilatation by the fact that they are not attended with ill-health. Gastric dilatation that is dependent upon duodenal obstruction may be recognized by the fact that the patient vomits bile—since the obstruction is usually placed below the orifice of the common bile duct—while in cases of pyloric stenosis the vomited matters are free from admixture with the biliary excretion.

The prognosis in this disease is always doubtful. While dilatation is caused by ma-

lignant obstruction of the pylorus, death is inevitable. Under the most favorable circumstances, relapses are frequent and cures are uncertain.

For the treatment of gastric dilatation the first thing to be attempted is the emptying of the stomach. This can be most easily and safely accomplished by the use of a soft rubber stomach tube, to the upper end of which a funnel is attached. Considerable difficulty usually attends the introduction of the tube before the patient has become accustomed to its intrusion into the pharynx, but with a little practise he learns to swallow the pliable siphon without irritating the nervous centers for retching and vomiting. Once carried to the bottom of the stomach, water of a temperature of about 90° F. should be poured into the funnel until it ceases to flow rapidly into the tube, or until the patient complains of too great pressure. The funnel should then be inverted and lowered below the level of the stomach, the tube being compressed by the thumb and finger of the operator, until the necessary adjustment of everything has been completed. Removal of pressure from the tube is then promptly followed by the evacuation of the contents of the stomach through the tube, which is thus converted into a siphon. If the opening of the tube should be obstructed by the entrance of fragments of food, it may be cleared by pouring a little water into the funnel, or by raising it up and down, or by making pressure with the hand over the gastric region. So long as the water that returns is turbid the operation should be repeated—filling and emptying the stomach until its cavity is thoroughly cleared. It may then be washed out with a solution of table salt—a drachm to the pint—or with a similar solution of Carlsbad salt—a half drachm to the pint. In this way the stomach may be completely relieved of its fermenting contents. The siphon tube is preferable for this purpose rather than the stomach pump, which is less convenient and much more liable to wound the gastric mucous membrane. In all these operations great care must be taken to avoid violence to the mucosa, otherwise the appearance of detached fragments of membrane in the wash-water will not be uncommon. Certain experts would have us believe that such evidences of injury are symptomatic of special forms of disease within the stomach, but this is doubtful. Under any circumstances the passage of sounds and tubes into an unsophisticated stomach is no trifling matter. Patients sometimes become

convulsed and unconscious when thus treated for the first time; but usually they soon become accustomed to the contact of a siphon tube and find great relief through the removal of the offending matters. The renewal of decomposition may then be at least delayed by the administration of drugs that arrest fermentation, such as sodium salicylate, resorcin, creosote, benzosol, and carbolic acid. The daily use of the siphon should be continued until satisfactory evidence of improvement is apparent. It may then be introduced every other day, and with less frequency as the case progresses more favorably. In all cases the treatment must be continued for a long time, and when the disease is caused by pyloric obstruction, it is impossible to lay aside the tube before the end of life, unless the difficulty can be removed by a surgical operation upon the pylorus. Patients can be taught to introduce the tube and to wash out the stomach themselves, but as a general thing the physician should maintain a careful supervision of the case in order to prevent mechanical injury of the food passages or to avoid the effects of ignorant use of healing methods.

Having provided for the cleansing of the stomach, it is needful to take measures for increasing the tone and vigor of its muscular coat. For this purpose the patient should remain in bed for several hours after each operation of lavage, and should apply to the epigastrium and gastric region an ice bag wrapped in a napkin. A sponge bath with cold water should be taken every morning on rising and on retiring at night. If so situated that he can use shower baths of cold water they should be taken every day—preferably in the morning. If the patient is feeble and over-sensitive he should stand in a little warm water while taking the bath. Daily massage of the whole body is another valuable means of increasing the muscular tone of weakly individuals. Light gymnastic exercises and walking in the open air must be enjoined, and the patient must be taught to aim at procuring at least two hours of such exercise—an hour in the morning and another in the evening. If the heart and kidneys are free from disease, horseback exercise and moderate bicycling will be found useful. The daily application of faradic electricity—placing one pole behind the spleen and moving the other over the region of the stomach for five minutes once or twice a day—is often very beneficial. Good results are also derived from intra-ventricular faradization—passing

one electrode into the stomach while the other is applied externally in the usual way. But one should be very sure of the loyalty of his patient before employing this method.

The patient must receive his food in small quantities every two hours. Liquids must be largely withdrawn from the diet list. Thirst may be relieved by rectal injections of cold water thrown high up into the colon with a long tube. Sugar, starch, and fat should be given in very small quantity, because of their tendency to fermentation. The food should consist chiefly of tender meat well minced, toasted bread, milk, soft-boiled eggs, oysters, and concentrated broths. As improvement appears a larger variety may be gradually introduced.

In the administration of medicine it is necessary to provide for an increase of motor and digestive power while endeavoring to prevent the process of fermentation in the gastric contents. For the first object, one-fiftieth of a grain of nitrate of strychnine may be injected hypodermically every six hours. Ten drops of dilute hydrochloric acid should be taken in four ounces of hot water after the three principal meals each day. One-half hour before each of those meals the patient should take five grains of salol or of salicylic acid, or a grain of resorcin or of carbolic acid, or five grains of sodium hyposulphite, to check the fermentative process during the approaching period of attempted digestion. As soon as the patient begins to feel able to remain for a considerable time in the open air the anemia that is present may be controlled with large doses of carbonate of iron.

Recently the aid of surgery was invoked with some degree of success for the relief of those forms of gastric dilatation that are dependent upon stenosis of the pylorus. Notwithstanding the high degree of mortality, it is sometimes the only resource, and fortunately with increasing experience the death rate is slightly diminished. In certain obstinate cases without pyloric obstruction the operation of folding the anterior wall of the stomach upon itself and sewing the border of the greatest curvature to the margin of the upper curve of the organ—just as a sailor takes a reef in a sail—has been performed with tolerable success.

---

*BRUNS ON THE EVOLUTION OF THE  
MODERN TREATMENT OF GOITRE.*

Two years ago the only treatment in vogue for goitre was the old and untrustworthy

remedy, iodine. At the Sixth Congress of German Surgeons, in the year 1877, attention was called by Rose, based on his own experience, to the radical cure of goitre by extirpation. This communication was particularly timely as the beginning of the antiseptic era prepared the ground for the greatest surgical undertakings. It is interesting to note how rapidly the excision of the thyroid and improved results followed. In twenty-seven years prior to 1877 only 150 excisions of the thyroid had been recorded, with a mortality of twenty-one per cent.; while in the five years following 1877 there were 240 operations, with twelve per cent. mortality.

Operations for extirpation of the thyroid lost their greatest drawbacks and dangers—secondary hemorrhage and wound infection—not only with the development of antiseptic measures, but also with the perfection of methods and technique of operation.

Prior to this time the operation had been conducted as in ordinary extirpation of a tumor, the goitre being superficially isolated and all blood-vessels ligated as cut, the result being that the same vessel was often divided in different places and required repeated ligation.

The separation of the cellular tissue was often pursued too far, resulting in extensive bleeding, requiring ligatures *en masse*, obscuring the entire operative field, and jeopardizing the nerve-trunks. This uncertain method of atypical tumor extirpation was now transformed into the typical extirpation of a viscus, an absolutely safe operation, and for the experienced operator a bloodless and complete procedure. The credit of devising a systematic operation belongs, above all, to Billroth, and next to Kocher, who essentially perfected it. It depends on the certain principle of exact anatomical knowledge concerning the course of the arteries and veins of the thyroid, and of the recurrent nerve, so that the essential object of the operation is the typical exposure and isolated ligation of the main arteries and veins at their well-known situations, and the speedy and bloodless isolation of the tumor.

Another important advance was the experience demonstrating the needlessness of tracheotomy, which many operators formerly had considered absolutely necessary in facilitating excision of the goitre and preventing the after-collapse of the trachea. Tracheotomy not only interferes with aseptic wound-healing, but before as well as after excision of thyroid it is absolutely unnecessary, even

in the greatest degree of compression of the trachea. The respiratory disturbances immediately subside after removal of the goitre. It may be laid down as a rule that even in the greatest dyspnea and danger of suffocation the operation which is indicated is not immediate tracheotomy, but immediate extirpation of the goitre. The total extirpation of the thyroid as a radical cure, as recommended by Rose, advanced in favor more and more, and reports of 400 such cases were recorded. Its popularity was due to the belief that it prevented recurrence from remaining portions of the gland, and apparently was attended with no greater difficulty and danger than the partial operation. No doubt existed as to the propriety of removing the whole organ, as at that time the physiological importance of the thyroid was not known. Very soon, however, came the reports of severe after-effects of total operation, such as tetanic convulsions severe enough to cause death, and that chain of manifestations included under the term "cretinism." An early report from Reverdin, in 1882, failed to attract attention. The next year, at the Twelfth Congress, Kocher communicated his report on "Cachexia Strumipriva," which made a marked impression. Surgical opinion did not at once universally accede to these views as to the existence and cause of the disease, and not until numerous victims of this condition had been discovered was this long-neglected gland recognized as an important vital organ. Total excision of the thyroid, formerly the routine procedure, was at once and forever stricken out as an operation of physiological incompatibility. Conservative surgical methods were now sought for, having for their object the removing of the goitre, but not of the entire thyroid gland. A time-honored method of treatment inaugurated at the beginning of the century by Philip von Walther, and lately revived by Wolfier, now came into vogue. This is the typical ligature of the thyroid arteries to promote artificial atrophy of the gland. The operation was, however, scarcely performed fifty times in the last decade, having attracted little attention except as a purely theoretical measure, for the richness and irregularity of the vascular supply of the thyroid make the task practically hopeless. An operation which was destined to receive quite a different degree of attention now came to the front. The operation of enucleation, which had occasionally been practised by some surgeons in the case of the cystic variety since its recog-

nition by the Italian surgeon Porta in 1840, was now established by Socin as a typical method even in treating the solid forms of goitre. The method received immediate acceptance, and constitutes to-day one of the most notable developments of modern thyroid surgery. Instead of stopping short on the surface of the gland for fear of wounding its veins, in Socin's method the parenchyma of the gland is deliberately divided till the cyst lies exposed, and this is then shelled out by blunt dissection, entailing no loss of normal glandular tissue. The essential principle of the operation lies in accurately locating the capsule of the cyst and keeping absolutely close to it without encroaching on the surrounding glandular tissue and its numerous delicate blood-vessels—a procedure requiring the greatest patience and technical skill. Very often, however, enucleation is quickly performed, accompanied by little bleeding, without nerve lesion, and the wound healing undisturbed. The operator must have a clear perception of the limitation of the operation of enucleation. It is undoubtedly the normal procedure in the less vascular cystic variety, as well as in the solid forms where the nodules are loosely attached and the capsules clearly defined; and, likewise, it is absolutely indicated in goitre involving both sides of the gland where the preservation of gland tissue on one or both sides is shown to be necessary. The operation must not be undertaken when it is impossible to recognize a definite demarcation between the normal gland tissue and the diseased nodules, or where extensive adhesions are present. Here the procedure is attended with a profuse or uncontrollable hemorrhage. The character of the operation is terrifying, and not infrequently cannot be carried out to a finish.

We possess in resection of the thyroid a procedure which replaces enucleation where the latter is contraindicated. It has the advantage over enucleation of efficient hemostasis, and over extirpation in the preservation of normal glandular tissue. Its chief advantage lies in the possibility of varying the method of operating. Sometimes the hilus or the isthmus can be left, or else the lower portion. It can also be combined to great advantage with enucleation. Mikulicz was the first to perform resection of the entire one-half of goitre as a typical operation.

As regards the results of the modern operations it can be briefly stated that to-day operations for non-malignant forms of goitre are practically without danger, provided in-

terference is resorted to before the advent of serious pulmonary and cardiac complications attending long-continued changes in the gland. It must be acknowledged, however, as regards the ultimate results, that the partial operations have been attended with a considerable proportion of unfavorable results, owing to the frequency with which both diseased and normal glandular tissue is preserved. The recent investigations leave no doubt that the number of recurrences after operations for goitre considerably exceeds our expectations.

It is noteworthy, however, that notwithstanding the numerous recurrences secondary operations are but seldom called for. The statistics of 800 operations furnished by the cases of Socin, Kroenlin, Krappeler, and the author have in scarcely a dozen cases required operation for recurrence. We are justified in considering operation for the relief of goitre as one of the most useful surgical methods at our disposal, as it brings about an immediate disappearance of the most terrifying asphyxia, and is attended with a result so radical as usually to hold good for the entire existence of the individual.

#### *INTESTINAL ANASTOMOSIS BY THE MURPHY BUTTON.*

DUNN (*International Journal of Surgery*, March, 1897) reports the following interesting case:

About 2 P.M. January 1, 1896, a nurse, aged twenty-five, was taken suddenly, while lifting, with a severe pain in her right groin. Having experienced similar transient attacks twice before, she went to bed, applied hot applications, and awaited Dr. Dunn's arrival. On his arrival at 10 A.M. on the 2d he found her suffering from a strangulated femoral hernia.

After an hour's delay, at the patient's request, operation under chloroform narcosis was undertaken. The pain and distress had evidently been pretty severe during the twenty-one hours of strangulation, but there had been little vomiting, and the incarceration was so brief that he was taken by surprise, on opening the sac, at finding three inches of small intestine, its only contents, apparently gangrenous. The opening was enlarged sufficiently to relieve all constriction, the loop drawn further down, and warm, moist compresses applied for twenty minutes, when it became perfectly evident that the loop of intestine was necrotic, and that a re-

section of a trifle over three inches of small intestine must be resorted to. The segment was cut out with scissors between the fingers of an assistant and an end-to-end anastomosis with a Murphy button readily established in about ten minutes. The intestine was then returned, the deep parts closed with fine silver-wire buried sutures, and the skin by a continuous subcuticular silkworm-gut suture. The patient made a perfect recovery, without vomiting, pain, febrile reaction, or other disturbance. The button was passed on the eleventh day. The subcutaneous stitch was withdrawn on the fourteenth day. She kept the bed for four weeks, when she resumed her duties as nurse, and up to date (thirteen months) has been in perfect health, without recurrence of the hernia, or any disturbance of the gastro-intestinal tract. The buried wire sutures have caused no irritation; though in one or two other instances among many cases in which the writer has used them they have been the cause of slight discomfort at times.

The writer has had occasion to use the Murphy button in seven operations, viz.: two cholecystenterotomies, two gastro-enterotomies, one end-to-end anastomosis of small intestine, one entero-colotomy, and one anastomosis of end of resected ileum to the side of the ascending colon. Excluding the latter case, in which no treatment could have hoped to avail, the button has served him with the utmost satisfaction.

After some experience with the various sutures, plates, and the button, he concludes:

1. No other method of anastomosis can compare in rapidity and ease with that by the button. None requires so little destructive handling of the viscera, none so conservative asepsis in handling an open intestine.

2. A good button applied with skill is more trustworthy against leak and slip than the stitching of any surgeon, however skilful.

3. On its separation (which appears to be pretty uniform at about ten or twelve days) no foreign substance is left in the tissues, and while present it does not act as a septic seton to convey infection into the tissues, as deep sutures must do.

4. The scar is but a fine line scarcely discoverable on the peritoneal surface, and with a minimum of connective tissue. The opening, a trifle larger than the button, presents every guarantee possible to any reunion against contraction, viz., a rapid, aseptic, and complete healing, which cannot lead to progressive contraction unless disease subse-

quently attacks the scar. It is a ragged, delayed, septic wound which leads to cicatricial contraction. There seem to be many objections still urged against the button, most of them theoretical rather than practical. Any one who has used or even seen the button used must admit the wonderful rapidity and ease of executing these operations by its use. It is difficult to see how any mechanical mind can doubt its greater accuracy of coaptation. That its work is more liable to progressive contraction than any other method of reunion whatsoever is disproven by both experience and theoretical deduction from known pathological principles.

Of all the objections which have come to my knowledge but two would appear worthy of much credence, viz.: 1. In a few cases, especially of gastro-enterotomy, the button has failed to pass. Under ordinary circumstances, when the opening is at the most dependent part of the large viscus, this accident must be rare. As already observed, the button has been promptly recovered in each of my cases; and a large experience of the profession in general has amply demonstrated that under ordinary conditions no apprehension need be exercised on this score. Under conditions which might excite a fear of the button falling into a cul-de-sac powerless to expel it, further modifications in the operative technique will, doubtless, prevent this accident. Dr. W. J. Mayo, of Rochester, Minn., has suggested attaching a thread of considerable length to the button and carrying it into the distal portion of the intestinal tract, as a "hold" for the peristaltic force of the tract. The suggestion seems sensible, and may prove useful in certain gastro- and cholecystenterotomies, in which a powerless pocket awaits the loosened button, should it drop off on the wrong side. 2. Some have feared that the small opening in and the weight of the button might lead to acute obstruction. Certainly experience has shown this to be more theoretical than practical. Obstructions after abdominal operations, from one cause or another, occasionally occur; but they have not been especially frequent after the button.

In short, if he were under the unpleasant necessity of having to undergo an anastomotic operation upon his own primæ viæ, he would doubly prefer to trust to the risks of the button than those of any suture or any device yet discovered in the hands of any operator.

## TUBERCULIN.

KOCH, in a comparatively recent communication to the *Deutsche Medicinische Wochenschrift*, again calls attention to the fact that his old tuberculin does not affect the bacilli of the disease, but simply immunizes against the toxins. He now believes that he has discovered a derivative which causes no systemic reaction, which immunizes, and which will cure cases of beginning tuberculosis. That this can be done in animals is proven conclusively. In the application of the method to man injections are given every other day, beginning with a dose of .002 milligramme a day and gradually increasing to .5 milligramme. During the period when the dose is being increased a careful watch must be kept upon the temperature, which should not rise even one degree. On the slightest febrile tendency treatment must be discontinued until the temperature drops to normal. When tuberculosis is complicated by infection with streptococcus the effect of the treatment is likely to be disappointing, and indeed it is scarcely indicated in those cases which exhibit a temperature of 100.5° F. It is thus apparent that the method may have its most valuable indications in the treatment of local tuberculosis, such for instance as that which develops on the surfaces. Indeed, it is in this class of cases that Koch has had his best results.

The drug can be procured in glycerin solution, each centimeter of which contains a milligramme. The minute initial doses are obtained by diluting this extract with a normal salt solution.

---

THE DIAGNOSIS AND PROGNOSIS OF  
CHRONIC GONORRHEA.

That little dependence can be placed upon the mere cover-glass preparation of urethral threads, by staining and microscopic examination with its attendant time-consuming labor, because the absence of the gonococcus in those preparations examined does not justify us in pronouncing a case free, has been recognized now for a long time, and yet is probably the only method pursued by a majority of physicians to-day to establish the fact of the presence or absence of this germ. Its absolute worthlessness was startlingly illustrated by KOPP in a paper read by him in September, 1893, before an association of German scientists and physicians, in which he reported seven cases of young men with chronic trouble where he had pursued this

method of examination alone, and after making in each case a series of from sixteen to twenty-five examinations and not finding the gonococcus, had allowed marriage. In all seven cases the wives, shortly after marriage, were found to be infected, gonococci being found in their secretions.

About this time Von Schlen, of Hanover, described his "third-glass test" for obtaining secretions from the prostatic follicles. After the patient has held his urine three to four hours he is to urinate into two glasses after the old method, and still to retain some urine in the bladder; with the finger passed into the rectum, by pressure and massage of the prostate its contents are pressed out into the urethra; the patient then urinates into a third glass. This method will afford a further collection of material for examination, and also suggests a method of treatment which has been put into practise by many—namely, massage of the prostate.

Independently and about this time Dr. Fuller described his method of examination and treatment for seminal vesiculitis, showing the dependence, in many cases, of persistent urethral discharges upon this condition. There can be no question that many cases in which gonorrheal disease is supposed to have disappeared may be found having a chronic inflammation of these organs, prostate, and seminal vesicles; or, if not a chronic inflammation, at least harboring pathological material. And yet the urine passed into two glasses, as ordinarily done, will be found to be clear or will show a faint, floating mucous shred, which when stained will reveal only mucus, a few epithelial cells, and perhaps here and there a leucocyte; but no gonococci will be found after the most prolonged search. These cases are thoroughly capable of transmitting the disease, and the fact perhaps will account for some cases of post-nuptial infection, where the husband was supposed to have been cured.

The question of the superiority of culture tests over microscopical examinations for the detection of the gonococcus may readily be admitted, but sufficient work has not yet been done along these lines to establish this superiority thoroughly. One of the most valuable contributions to this side of the question is that by Dr. Heiman, in which he gives the results of a series of examinations of chronic urethral threads by both the microscope and by culture tests in sixty-one cases. A glance at his tables, however, gives us a genuine surprise—that is, the very slight superiority

which the examinations by means of culture experiments have over the examinations by means of the microscope for the detection of this micro-organism.

Out of sixty-one cases, gonococci were detected by means of the microscope in thirteen, while by means of culture media in only fourteen cases was their presence established; so that unless the method of examination by cultivation can be proved to be easier, shorter, less tedious, and more certain, unless we can feel that we can rely upon it with greater confidence, but few will be tempted to add a culture plant to our ever-increasing armament. In medico-legal cases, of course, the culture experiments could not be omitted.

Heiman gives some valuable hints in the methods employed for the collection of the materials to be examined. He had the patients urinate in small sterilized tubes, which were placed in the centrifuge, thus quickly collecting all the material for examination. His work, however, is far from being finished; there are two portions at least of the genito-urinary tract on which some one must spend his time and patience, namely, culture experiments placed side by side with microscopic examinations of material obtained from the glands of Littre and the pockets of Morgagni, and from the seminal vesicles. Then, too, though Dr. Heiman in his cases includes examination of material from the prostate, a perusal of his article would lead one to suppose that this was not certainly done in a thorough manner. The prostate was pressed upon with the finger while the patient was urinating; it does not seem as if this would express the material sufficiently—in fact, it is not the best way to accomplish the purpose. The expression should be made while there is urine in the bladder, but not during urination.

The microscopic examination and detection of gonococci in material expressed from the glands of Littre and Morgagni, and from the prostatic follicles, separating this from that which comes readily from the urethra, has already been done in a series of cases by Pezzoli in Finfer's clinic. The method of separation of material from different portions of the canal was ingenious, and of course requires patience and considerable training. First the anterior urethra is irrigated by means of a retrojection catheter with distilled water, the washings caught in a glass vessel and labeled (*a*), material from anterior urethra. Then the patient lies on the table, and the largest size *bougie a boule* capable of pass-

ing the meatus is passed down to the bulb, with the penis laid over the tubes. One hand of the operator gently presses the organ, and the instrument is moved back and forth several times from bulb to meatus. The urethra is again irrigated with distilled water, the washings caught and labeled (*b*). These are the expressed contents of the urethral glands and pockets. Then the patient urinates into one glass labeled (*c*); this contains threads from the posterior urethra. Then, if the urine be clear (*i.e.*, the urine still remaining in the bladder), the prostate is massaged, and he urinates into another glass labeled (*d*). This represents material from the prostate. If the urine is all cloudy the bladder is emptied and then filled with a normal salt solution before the prostate is massaged.

The material in these four receptacles is collected by the centrifuge or by filtration. Pezzoli made all his examinations by the microscope alone, but he established the following points: 1. That the urethral glands and pockets in the acute stages of a gonorrhea are almost without exception affected. 2. That in cases of chronic anterior urethritis gonococci will be found more frequently in the glands of Littre and the pockets of Morgagni than in the anterior urethra itself. 3. That in chronic posterior urethritis the prostatic follicles are also involved almost without exception.

It would seem as if a most valuable study could be made, after this manner, by placing culture experiments side by side with the microscopic findings.

In forming a final judgment as to the probable disappearance of gonococci, the value of an irritant injection of either silver nitrate or bichloride of mercury solution must not be forgotten; but this can only be of value in the anterior urethra and its glands, for gonococci in the recesses of the prostatic follicles or in the seminal vesicles need not necessarily be awakened by the traumatic anterior urethritis evoked by the irritant injection.—*Journal of Cutaneous and Genito-Urinary Diseases*, March, 1897.

#### INTERNAL STRANGULATION FOLLOWING UPON RESECTION OF THE INTESTINE.

Within the last two months cases have been recorded by HEIDENHAIN and by BRAUN in which a patient, after recovery from an operation involving the removal of a portion of the intestine, has developed

symptoms of intestinal obstruction. In operating for the latter condition it was found in each of the two cases that a gap had been left at the first operation between the divided mesentery and the intestine, through which one or more coils of bowel had passed and become strangulated. In Heidenhain's case this took place seven weeks after the first operation; in Braun's case there was an interval of five years between the original resection of the bowel for a gangrenous hernia and the subsequent internal strangulation. In operating for the latter condition it was found that a portion of the small intestine, seven feet in length, had passed through the gap which had been left at the original operation between the mesentery and the intestine and the point at which the latter had been resected and reunited, and had become twisted upon itself and strangulated. It is therefore essential, in all cases in which a portion of bowel is resected, that this gap should be accurately closed, in order to prevent the later occurrence of internal strangulation.—*Edinburgh Medical Journal*, April, 1897.

#### TREATMENT OF OLD FRACTURES OF THE PATELLA.

SUBERCAZE (*Thèse de Paris*, No. 23, 1896-97) holds that unless the interval be very short cure is hardly possible without surgical intervention, which should be undertaken as soon as the formation of callus is nearly or quite over—that is, about three months after the injury. If extension be deficient, the fragments should be united by suture. If they cannot be brought together he recommends osteotomy of the tuberosity of the tibia, or section of the tendon of the patella. In other cases the upper fragment of the entire patella may have to be removed. Cautious early movements (ten days after operation), and progressive exercise, massage, and electricity may give good results.—*British Medical Journal*, March 27, 1897.

#### ASEPSIS AND ANESTHESIA IN URETHRAL SURGERY.

Dr. JOHN A. WYETH, in the *New England Medical Monthly* for January, treats of the modern technique of urethral surgery, noting that two important branches of the subject are worthy of closer attention than they commonly receive. The first and most important is urethral asepsis. A urethra which is about to be incised should be made sterile, if this is

possible, and the urine of such a patient should always be sterilized at least twenty-four hours before the operation, and should be kept sterile during the time of treatment. We recognize the fact that the so-called "urethral fever" is a form of septic infection. The administration of twenty drops of a mixture of one drachm of salol and two drachms of oil of gaultheria, three or four times a day, will sterilize the urine within twenty-four hours. It is also claimed that the administration of boracic acid, five grains four or five times a day, will effect the same result, but the author has used the first formula with such satisfaction that he has never tried the boracic acid. We are indebted to the late Prof. R. Palmer of Louisville, Ky., for popularizing this important point in treatment. In addition to this the urethra should be irrigated with permanganate of potash (1:3000) for five minutes before the operation, or it should be thoroughly "ballooned" with this antiseptic solution by using the ordinary conical syringe introduced at the meatus, and the canal thoroughly distended with the fluid. This should be repeated three or four times, and a sufficient pressure employed to overcome the resistance of the cut-off muscle, in this way reaching the entire canal.

The second point is the question of anesthesia. The vast majority of all strictures of the urethra can be treated practically without pain with cocaine anesthesia. From the meatus to the cut-off muscle the urethra can be anesthetized by using from one to three drachms of a two- or four-per-cent. solution. The writer gives varying quantities and strengths of solution, because no given prescription would fit every case. It is his rule to study carefully the susceptibility of every new patient to this agent, and disregard of this rule has given the unfortunate results that now and then find their way into the journals. When the entire urethra is injected, one drachm of a two-per-cent. solution should first be employed, and the degree of the susceptibility of the patient, as well as the anesthetic effect produced, can be ascertained in five or ten minutes. If the anesthesia is incomplete and the patient shows no susceptibility to the drug, another drachm of the same or a stronger solution may be injected. It is also very important to remember that a patient is much more susceptible to the absorption of cocaine when it is employed for the introduction of sounds for the first few times after than at the time of the operation, for the simple reason that an incision more

or less extensive has been made, which incision is covered with granulation tissue, rich in capillaries and ready and capable of absorbing under pressure a considerable quantity of cocaine. Anesthesia of the membranous portion of the urethra may be obtained by carrying the Keyes-Ultzman syringe point down to the cut-off muscle, pushing it slightly within, and injecting ten to fifteen minims of a four-per-cent. solution. Anesthesia beyond the cut-off muscle is practically impossible, for the reason that the urine is in contact with this portion of the urethra and so dilutes the cocaine as to make it practically inefficacious. In meatotomy a few crystals applied just within the meatus, or ten minims of a six-per-cent. solution injected, limiting the application by digital closure of the canal one inch behind the opening, will effect complete anesthesia in division of the meatus or of an organic stricture here.—*Journal of the American Medical Association*, March 20, 1897.

#### BONES FRACTURED BY MUSCULAR ACTION.

Dr. C. J. EDGAR, in the *Montreal Medical Journal*, reports an interesting and unusual case of fracture of the scapula by muscular action alone. A man aged about forty-five, tall, spare but muscular, was driving a heavily laden team down a somewhat steep incline and walking beside the load, when part of the harness broke, and to prevent the wagon running upon the horses he caught hold of one wheel by the spokes with both hands. The impetus, however, was too great, and he was gradually forced over and down upon one knee. As his knee touched the ground he felt something give way in his left shoulder, and lost his hold. On rising to his feet he found the arm powerless and very painful, the pain being referred to the shoulder joint, which he thought to be dislocated. On manipulation of the scapula it was found that the entire inferior angle was torn away and separated from the rest of the bone by half or three-quarters of an inch. Firm union was secured in seven weeks, leaving however a very marked ridge of callus over the seat of fracture. Motion was perfect, and the arm regained all its former usefulness. A case has been recently reported from San Francisco, in which the pitcher of a baseball club fractured his humerus in three places by the effort he put forth in throwing a line ball from third to first base. And within ten days thereafter another similar case occurred at

the same place, the fluoroscope showing a double fracture of the bone.—*Medical News*, March 20, 1897.

#### LEFT TRAUMATIC SUBCLAVIO-AXILLARY ANEURISM CURED BY LIGATURE OF THE THIRD PORTION OF THE SUBCLAVIAN ARTERY.

HEUSTON, in the *British Medical Journal* of March 20, 1897, reports the following interesting case:

A. N., a pensioner aged fifty years, was placed under the writer's care at the Adelaide Hospital by Surgeon-Major F. A. B. Daly. He had served in the army for twenty-one years, during eighteen of which he was in the band as a clarinet player, and was discharged from the service in July, 1887, in good health. In the summer of 1892 a heavy board fell on his left shoulder, and although he had no pain until May, 1895, he attributes his affection to this accident. In November, 1895, he consulted Surgeon-Major Daly for pain in the left shoulder, clavicular and scapular regions. The superficial veins over the left clavicle were slightly enlarged, and a slight difference was noticed in the radial pulses, but no bruit could be obtained. Aneurism being suspected, he was given large doses of potassium iodide, and his diet was regulated. This treatment gave such relief that he resumed his work as night porter at the United Service Club.

In January, 1896, the pain in the shoulder and back returned with increased violence, and at times shot down the left arm and to the region of the diaphragm. He was then admitted to a civil hospital in this city, but was soon discharged without relief, his case not being recognized. He then again consulted Surgeon-Major Daly, who found his symptoms to be much better marked than when he saw him before, and that a well-marked tumor had developed in the left posterior inferior triangle of his neck.

The patient was admitted to the Adelaide Hospital under the writer's charge on February 26, 1896. He is a well-built, healthy-looking man, and stated he had a severe continuous pain in his left shoulder and back, in the region of the scapula. This pain was relieved by placing his arm over his head. The left arm was greatly swollen and edematous, its superficial veins were markedly distended and tortuous, the left clavicle was raised, and the supra- and infra-clavicular depressions obliterated owing to a tumor which occupied the

subclavian triangle and the axilla as far as the lower border of the pectoralis minor. This tumor had a distensible pulsation, and well marked bruit and thrill. There was marked difference between the right and left radial pulse, and visible pulsation of the carotid and brachial arteries.

Ligature of the subclavian artery being decided on, the usual transverse incision for exposing the third portion was made, and the artery exposed as it passed from beneath the scalenus muscle. It was of normal appearance, but its sheath was very adherent. A strong catgut ligature was passed round the vessel and tied, the ends of the ligature being removed; the deep structures were united by hidden catgut sutures, and the skin by silkworm. The wound was dressed with zinc sulphite gauze, and the arm swathed in cotton-wool.

The subsequent progress requires little note. The wound healed by first intention, although a stitch abscess occurred at the site of the most anterior skin suture. Pulsation returned in the radial artery on the eighth day after operation, and the patient left hospital on the twenty-third day to resume his duties at the United Service Club.

The patient was shown at the Surgical Section of the Royal Academy of Medicine in Ireland on May 1, two months after operation. Since leaving hospital he had been engaged at his usual work as night porter. The left radial pulse was small, but the artery was of good tension. The tumor had lessened considerably in size, and had no pulsation or bruit. All the other symptoms had disappeared. Eleven months have now elapsed since operation, and the patient continues in perfect health.

On referring to Edmond Souchon's article on Aneurisms of the Subclavian Arteries in the *Annals of Surgery* for November and December, 1895, it will be found that out of 120 aneurisms of the third portion of the artery, thirty-five implicated that of the left and eighty-five that of the right side, and that of thirty-one traumatic aneurisms operated on by proximal ligature nineteen recovered (about sixty-six per cent.), four of these being on the right and fifteen on the left side.

#### TARDY TRAUMATIC STRICTURES OF THE URETHRA.

Professor BAZY describes a case and quotes one other on record, in which the symptoms of stricture were preceded by fracture of the

pubis forty and fifteen years previously. As the retention of urine was not complete the idea of prostatism was rendered less probable, and in exploring the urethra the bulb could not be felt through the rectum. He considers this fact a valuable means to differentiate spasm of the membranous portion from stricture located in the remotest part of the perineum, and thus close to the membranous portion. In his case the bladder was two finger-breadths above the umbilicus, prominent and painful. With a No. 23 blade he sectioned the stricture, which seemed as hard as any gonorrheal or other premembranous stricture, and the section was absolutely bloodless. Evidently a slow process of sclerosis had terminated in the production of a stricture. The treatment was successful.—*Journal of the American Medical Association*, March 10, 1897.

#### PREVENTION OF HEMORRHAGE IN OPERATIONS ON THE LIVER.

A couple of Russian surgeons, Kousnetzoff and Pensky, have been experimenting with a view to finding a process that would enable the liver to be resected without danger of hemorrhage. They now announce in the December *Revue de Chirurgie* that they have succeeded experimentally and in attempts on cadavers, and prophesy that ablation of large tumors and resection of part of the hepatic parenchyma will soon enter into current surgical practice. They find that ligature of the mass of the liver, slowly and firmly drawn tight, closes the lumen of the vessels and thus prevents hemorrhage. After chloroform the peritoneum is opened and the lobe of the liver drawn out through the wound. A row of ligatures is then made through the liver with a blunt needle and a double silk thread, the entire length of the piece to be removed. A sharp needle would injure the vessels and possibly produce hemorrhage. The needle is pushed into the mass of the liver and drawn out the other side. It is thus passed through the substance of the liver several times, a few centimeters apart. The holes made by the needles each contain therefore two threads, the ends extending out above and below. The nearest threads in the different holes are then tied together; one thread in a hole thus acts on the hepatic substance to the right of the hole, and the other to the left. When these ligatures are drawn tight, the piece to be resected in front or back of them is removed. If the ligatures have not been

drawn tight enough some vessels will bleed, when they must be separated and pulled up out of the parenchyma with a pair of Pean forceps and tied with a silk thread, or the surrounding tissue compressed with an intervening ligature. Compresses of gauze should be applied to control hemorrhage of the parenchyma. In secondary hemorrhage the bleeding surface may be thermo-cauterized after the row of ligatures has been made, but this is unsatisfactory and usually the vessels have to be tied finally. But hemorrhage rarely occurs if the ligatures through the hepatic mass have been drawn absolutely tight. After the ablation the hepatic stump is sutured to the end of the abdominal wound, or the great omentum can be sutured to the cut surface of the liver, or the stump can be put back into the abdominal cavity and the walls closed with a suture in three stages, after dressing with collodion gauze. This means of hemostasis is almost invariably successful; it can be supplemented by suturing the edges of the wound in the liver together, after interposing a gauze tampon, leaving the end of the tampon protruding from the cutaneous wound, and removing it in a few days in one or two sittings. Mikulicz has treated a case of syphiloma of the liver in this way with great success. Experience on the cadaver shows that the most convenient cutaneous incision is parallel to the arch of the false ribs, one or two finger-breadths below, ten to fifteen centimeters in length, starting at the right parasternal line for the right lobe, and at the median line, swerving to the left, for the left lobe.—*Journal of the American Medical Association*, March 20, 1897.

#### MASSAGE IN THE TREATMENT OF FRACTURES.

WOOLSEY (*Medical News*, March 20, 1897) concludes an article with the above heading with the following summary:

1. The treatment of such fractures, especially those near joints, by immobilization, whether ambulatory or not, leaves something to be desired in (a) the time required and (b) the functional result obtained.
2. The treatment of such fractures by massage and passive motion shortens the time of bony union by one-third or one-half, and vastly improves the immediate functional result.
3. This treatment is especially applicable and important in fractures near joints.
4. Its application is easy. It relieves pain

and swelling, hastens callus formation and solidification, prevents atrophy of the muscles and stiffness of the joints and tendons.

5. Splints should be applied between the daily fifteen- or twenty-minute applications of massage for the first ten or twenty days, according to the nature of the fracture and the tendency to displacement, or until consolidation occurs.

6. This treatment, combined with the ambulatory method, promises an ideal method.

7. Oblique fractures of both or the only bone in a limb, or fracture near the middle of the limb with a tendency to displacement, should be immobilized until consolidation has commenced.

8. The ambulatory treatment is indicated in the latter classes of fractures, in fractures of the lower extremity in the alcoholic or very aged, and in fractures of the neck of the femur in the aged.

9. The plan of immobilizing the limb for a short time in the best possible position, and then applying massage and passive motion, promises equally good results, and especially adapts the method to private practice, in which it is particularly indicated on account of the shortened time required for union and the excellent functional results.

A SYSTEM OF MEDICINE BY MANY WRITERS. Edited by Thomas Clifford Allbutt, M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge. Volume II.  
New York and London: The Macmillan Company, 1897.

The second volume of this very notable encyclopedic work on Medicine, contributed to a very large extent by subjects of Her Majesty the Queen, is a fitting summary of English medical knowledge in her Jubilee year.

The present volume deals first with infective diseases of chronic course such as tuberculosis, leprosy, and actinomycosis. The first article, upon Tuberculosis, is an unusually short one for such an exhaustive work, covering only thirty-seven pages. Certainly one might expect a more diffuse and complete study of this disease in a volume of this character. The article is written by Dr. Sidney Martin, and considering its brevity is quite good. We are disappointed to find that less than eight lines are devoted to the treatment of tuberculosis, although it is only fair to state that the local treatment of tuberculosis by medic-

inal or surgical measures is considered elsewhere in this System. To us this article is perhaps the most disappointing that we have met with in the series. The second article by Dr. Abraham upon Actinomycosis is longer than that of Dr. Martin upon Tuberculosis, covering forty pages, and is completed by a useful and selected bibliography concerning this interesting disease. As an evidence of the unevenness of articles written by numerous contributors to one volume we may call attention to the fact that while two pages and a fraction are devoted by Dr. Abraham to the bibliography of actinomycosis only nine lines are given by Dr. Sidney Martin to the bibliography of tuberculosis. After considering the Infective Diseases of Chronic Course, we next come to the rather curious subdivision of Diseases of Uncertain Bacteriology. Under this classification is first considered the diseases which are endemic, and in this list is included measles, rubella, scarlet fever, chicken-pox, smallpox, mumps, whooping-cough, constitutional syphilis, and "the coincidence of infectious diseases." All of these articles are good, but we fail to find anything in them which is particularly worthy of note. In the second section of this subdivision are included the topical or endemic diseases of uncertain bacteriology. This chapter opens with an article by Sir Joseph Fayrer on the Climate and Some of the Fevers of India. It is followed by articles upon Yellow Fever, Typhus Fever, Dengue, Dysentery, Beriberi, Malta Fever, Epidemic Dropsy, Sleeping Sickness, Oriental Sore, Verruga and Framboesia.

The next section of the book is upon Infectious Diseases Communicable from Animals to Man, and in this is first considered Glanders or Farcy and then Anthrax. These two conditions are classed under the heading of "Certain Bacteriology," while Vaccinia, Foot and Mouth Disease, Rabies, and Glandular Fever are classified under the head of "Uncertain Bacteriology."

We fail to find in the text any reason for putting "Glandular Fever" under the head of "Infectious Diseases Communicable from Animals to Man." The articles upon Diseases Due to Protozoa are devoted to Malarial Fever, Hemoglobinuric Fever and Amœbic Dysentery; and in these chapters for the first time do we find American contributors, Dr. Osler writing the article upon Malarial Fever, and Dr. Lafleur, formerly of Baltimore and now of Montreal, contributing that upon Amœbic Dysentery. Both of these gentle-

men are well known for their original work upon these diseases, and the articles which they have written are of greater value than most of the others which the book contains. We think it unfortunate that in the article upon Dysentery by Andrew Davidson more frequent reference is not made to that of Dr. Lafleur upon Amœbic Dysentery.

We are glad to notice in the article upon Hemoglobinuric Fever that the author, Dr. Copeman, emphasizes the view that it is usually malarial in origin, and seems to side with those who believe that quinine is a harmful remedy during the attack.

The closing pages of the volume are devoted to the Intoxications, Animal, Vegetable, and Metallic; the Internal Parasites; and in an Addenda, in order that the volume may be up to the very latest information obtainable, we find additional statements concerning the serum diagnosis of typhoid fever, a supplement to the article on the Plague, and an addendum on Yellow Fever.

The volume closes with an index of authorities in which we are glad to see that the authors have frequently referred to American investigators, and with a short but closely printed index of subjects which is sufficiently exhaustive to afford us a good guide in turning to different portions of the book for information.

This second volume fully maintains the reputation obtained for this System by its predecessor and by the special volume on Gynecology belonging to this System, which have already been issued. Some delay has occurred in the publication of Volume II, which we are told is due to the late appearance of the report of the British Committee on Vaccination, the important work of which could not be ignored in the preparation of a volume such as that before us.

LIPPINCOTT'S MEDICAL DICTIONARY. A Complete Vocabulary of the Terms Used in Medicine and the Allied Sciences. Prepared on the basis of Thomas's Complete Medical Dictionary. By Ryland W. Greene, A.B. With the Editorial Collaboration of John Ashurst, Jr., M.D., LL.D., George A. Piersol, M.D., and Joseph P. Remington, Ph.M., F.C.S.

Philadelphia and London: The J. B. Lippincott Company, 1897.

Members of the medical and allied professions have certainly been provided with dictionaries to a most generous degree by the medical publishers of the United States within the last five years. The older and more familiar works have been revised until their pages contain, or try to contain, the latest definitions and other matters

of interest for which one would look in such a work of reference, and in addition to these revisions new and most valuable encyclopedic dictionaries have been prepared and published, all of which have been noticed from time to time in the review pages of the *GAZETTE*. One of the best of the dictionaries which have appeared within recent years was that of Dr. Thomas, which was more exhaustive than any dictionary of its time, save perhaps that of Dunglison; but the publication of new works soon caused this well known encyclopedia to be displaced, and we presume it is for this reason that the publishers have called to their aid such well known literary workers as the gentlemen who are named upon the title-page of this new edition. It is pointed out in the preface that a modern dictionary should invite, not repel, consultation, and therefore one's curiosity is roused to discover whether in the recognition of this fact the collaborators who have prepared this edition have made it attractive to the bibliophile. A careful examination of it seems to indicate that they have been successful, for the pages are broad, the type is of good size, and the words themselves are in black-faced types which are readily seen at a glance as they stand out in bold relief from the descriptive text. In the case of Latin words the English pronunciation has been given precedence as having the overwhelming weight of evidence in its favor; but in many cases, for the sake of emphasizing the increasing use of the Roman pronunciation, the latter has been given also after the English pronunciation, and is distinguished from the latter by the letter "L."

The collaborators' work was divided in such a way that Dr. Ashhurst undertook the branches of surgery and general medicine and gave special attention to the linguistic and literary portions of the volume, especially the etymology, pronunciation, and terminology. Dr. Piersol undertook the work in the parts of anatomy, histology, and embryology; while Professor Remington took charge of the important branches of pharmacy, materia medica, and chemistry.

The fact that Mr. Joseph McCreery read the proof of this volume is a guarantee that it is free from typographical and other blunders which the best of printing offices are sometimes guilty of making. We doubt whether it is correct to state that gaultheria is a stimulant and astringent; so far as we know its physiological action is identical

with that of salicylic acid, which does not possess these properties, and we think it would have been better to have emphasized the use of its oil in the treatment of rheumatism rather than to have mentioned its employment in chronic diarrhea.

When asked recently by a practitioner of medicine for advice as to the best dictionary for him to purchase, the writer of this review was at a loss to recommend any particular work in view of the equal value of a number of those at present on the market. We cannot say that this is the best dictionary that we have ever seen, but to those who wish to purchase a large and complete book of this character we can state that they will not make a mistake if they send for this work, which we can as cordially recommend as any dictionary in the English language.

**DISEASES OF THE EYE AND OPHTHALMOSCOPY.** A Hand-book for Physicians and Students. By Dr. A. Eugene Fick. Authorized Translation by Albert B. Hale, A.B., M.D. With a Glossary and 158 Illustrations.

Philadelphia: P. Blakiston, Son & Co., 1896.

The author's endeavor has been to produce a "compactly written book," suited to the needs of students and physicians who stand in awe of exhaustive treatises on ophthalmology. This is a commendable but difficult task, and Dr. Fick, in the reviewer's opinion, has not always successfully grappled with the law of just proportion. Three pages devoted to a description of A. Fick's tonometer, and less than two pages to the treatment of trachoma, indicate faulty judgment with reference to the relative value of the subject matter. Certain sections of the book are inadequate, notably those devoted to errors of refraction and to the management of trichiasis and entropion. Indeed, in general terms it may be said that the author has been much hampered by his desire to maintain brevity of description when he deals with operative procedures.

The advantages of the simple extraction of cataract are recognized, but Dr. Fick prefers the combined operation. Mules's operation is mentioned, but is not commended. Iridectomy is performed after iritis "if the adhesions are so plentiful or so extensive as to threaten a total synechia during any future relapse." Large sounds in the treatment of lachrymal disease are condemned, and the actual cautery is rarely employed in the management of severe corneal ulcer.

The sentence "In blenorrhoea of the newborn the disease, as a rule, runs its course

without attacking the cornea" is misleading. While it is true that under the guidance of competent medical advice, if the eye is seen while the cornea is still clear, except in those examples which assume a malignant type, the case should be brought to a successful termination, the prognosis is always grave and the assiduous attention of nurse and doctor is urgently demanded to save the eye from destruction. Ice poultices in this disease are considered "superfluous, if not harmful." If "ice poultices" mean properly applied iced compresses, the reviewer heartily disagrees with the author, and believes his advice is not only "superfluous," but "harmful."

While there are many excellent points in this book, while it reflects in a certain sense modern ophthalmology and particularly the views of its author, and while it may be read with profit by all students of ophthalmic science, it will not replace the many valuable American and English text-books on the same subject.

Dr. Hale's work has been well performed, and we think he has most wisely endeavored "to convey in English the exact idea expressed by the German." When the book reaches a second edition we trust he will assume a new function, viz. that of editor, and supply the subject matter which is required to render this a more acceptable book for American readers.

The book is well and clearly printed. The illustrations, 158 in number, some of which are colored, are mostly borrowed. Many of them are excellent; others are of indifferent value.

ENCYCLOPÆDIE DER THERAPIE. Herausgegeben von Oscar Liebreich unter Mitwirkung von Martin Mendelsohn und Arthur Wurzburg. Zweiter Band. I. Abtheilung.

Berlin: August Hirschwald, 1897.

During the last two years we have had occasion to review from time to time as they have appeared in medical literature the earlier fasciculi of this very valuable encyclopedia by Professor Liebreich and his well known colleagues. The present fasciculus is the first part of Volume II. It extends from "Diaphoretica" to "Flaschbouillon" and is compiled by the various collaborators that Professor Liebreich has associated with himself in this literary enterprise. As we have pointed out in previous reviews, this encyclopedia cannot be considered as being devoted solely to therapeutics, as it wanders far afield and studies etiology and pathology and many other matters which are of a great deal of in-

terest to the general practitioner but cannot be considered as being distinctly therapeutic. Considering the wide range of therapeutics as it exists to-day we are rather surprised that so much matter out of ordinary lines is included. These comments, however, are not made in the light of criticism; they are simply due to our amazement at the never ceasing industry of Professor Liebreich. We hope that future fasciculi may appear more rapidly than have the last five.

Upon the completion of the volumes *in toto* the medical profession will be presented with a very valuable compendium of medical information.

HYSTERIA AND CERTAIN ALLIED CONDITIONS: THEIR NATURE AND TREATMENT, WITH SPECIAL REFERENCE TO THE APPLICATION OF THE REST-CURE, MASSAGE, AND ELECTRO-THERAPY. By George M. Preston, M.D. Illustrated.

Philadelphia: P. Blakiston, Son & Co., 1897.

The author of this book in his preface makes an apology for his publication, which we think is always a mistake. After reading it we are somewhat at a loss to know why it was thought necessary to place upon the market a separate volume devoted to the consideration of such a disease as hysteria, accounts of which can be found in most good text-books on the Practice of Medicine and Nervous Diseases.

An examination of the Table of Contents shows that the first chapter is devoted to the consideration of the History of Hysteria; the second to the Nature of Hysteria, its Etiology and Pathology; the third to its Symptomatology; and the fourth to Disturbances of Motion. Subsequent chapters are devoted to discussions on convulsive attacks, the mental condition of hysteria, visceral and vaso-motor disturbances, differential diagnosis, treatment, electro-therapy, and other various forms of treatment; while the eleventh chapter of the volume presents a dissertation upon rest-cure, hypnotism, and surgical interference in the treatment of hysteria. An index completes this comparatively short and not very exhaustive volume.

SURGERY OF THE RECTUM AND PELVIS. By Charles B. Kelsey, A.M., M.D. Illustrated.

New York: Richard Kettles & Co.

The surgeon is at once struck by the change of title in this book and its increased scope. For years Kelsey has been the authority on rectal disease and his work has been the standard on this subject. Indeed it is more thorough and practical than any similar book in any language. At first glance the

inclusion of, for instance, intestinal resection and anastomosis, salpingectomy, oophorectomy by abdominal incision, fixation of the uterus, the radical cure of hernia, operations on the male genito-urinary organs, the surgery of the ureters, and appendicitis, would seem to be foreign to the subject. In his preface, however, the author states that it is impossible to separate diseases of the rectum in practise from gynecology and genito-urinary diseases, and that he has simply followed what experience has proved to be the natural course of his own practise. It may be said that his chapters upon these topics are characterized by the same clearness of diction and soundness of judgment which have made his writings upon exclusively rectal diseases so universally acceptable.

The illustrations are profuse and admirable, and the book can be universally commended.

ATLAS AND ESSENTIALS OF GYNECOLOGY. By Dr. Oscar Schaeffer. Illustrated.  
New York: William Wood & Co., 1897.

The author states that he has written this book with the idea of giving the student and physician the material which personal clinical observation should supply. The first part is devoted to malformations and arrests of development. Next follows a section on changes of shape and position, inflammations and trophic disturbances, injuries and their sequelæ, and finally neoplasms. The book is profusely illustrated, containing sixty-four colored plates and many illustrations in the text. The number of pictures and the care with which they are described fully justifies the title of atlas; indeed the first half of the book is practically taken up entirely with pictures and their appropriate legends.

Diagnosis and treatment are briefly outlined. This work would be particularly valuable to those who are already familiar with the technique of gynecological manipulations and operations.

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS. In Photo-lithocromes from Models in the Museum of the Saint Louis Hospital, Paris. With Explanatory Woodcuts and Text. By Ernest Besnier, A. Fournier, Tenneson, Hallopeau, Du Castel, Henri Feulard, and L. Jacquet. Edited and annotated by J. J. Pringle, M.B., F.R.C.P.  
London: The Rebman Publishing Co., Ltd. Philadelphia: W. B. Saunders. 1897.

The ninth part of this admirable series contains four colored plates representing squamous eczema; pustular scabies; disseminated lupus affecting the ears, upper extremities,

and center of the face, with tuberculous synovitis; and gummatous tuberculous lymphangitis, secondary to tuberculous dactylitis.

In addition there are a number of excellent woodcuts. The subject matter is by Jacquet, Feulard, Besnier, and Thibierge. The latter, writing upon gummatous lymphangitis, states the fact that reinfection of tuberculous subjects through the skin is now perfectly recognized, thus contrasting with syphilis, which cannot be reinoculated. In a case reported there was tuberculous dactylitis associated with gummatous lymphangitis. The lesion on the finger was only one link of a long tuberculous chain. If it was the cause of tubercular lymphangitis it was also the immediate result of the pulmonary tuberculosis by auto-inoculations of the finger with products of the expectoration.

A CLINICAL, PATHOLOGICAL AND EXPERIMENTAL STUDY OF FRACTURE OF THE LOWER END OF THE RADIUS, WITH DISPLACEMENT OF THE CARPAL FRAGMENT TOWARD THE FLEXOR OR ANTERIOR SURFACE OF THE WRIST. By John B. Roberts, A.M., M.D. Illustrated.

Philadelphia: P. Blakiston, Son & Co., 1897.

There are few surgeons who have not been familiar for years with Dr. Roberts' original but thoroughly well founded teachings on the subject of fracture of the lower end of the radius. In the present volume the author by means of woodcuts, skiagraphs, the study of specimens and experimental observations thoroughly proves his position.

As to the treatment of the injury Roberts advises after complete reduction the application of retentive dressings which will not interfere with the free use of the fingers. He urges the necessity of thorough reduction and points out that this may require great force. He states that the surgeon "should grasp the metacarpus of the patient with one hand and the lower part of the forearm with the other. This should be done with the patient's hand in the supine position. The thumb of the surgeon's hand which holds the metacarpus should be placed on the palmar surface of the carpal fragment of the radius as it lies just behind the thenar eminence. Extension and counter-extension are to be made for a moment; the hand should then be suddenly bent backward in strong dorsal flexion, and at the same instant the surgeon's thumb should push the lower fragment backward into place. This can be done in a moment and will not require anesthesia. It will be exceedingly painful, but is so quickly done

that as a rule etherization is unnecessary. If sufficient force is applied the fragments will be driven into place at once with a coarse grating sensation. Occasionally a repetition of the manipulation may be needed to obtain perfect restoration of the bony contour.

"This manipulation is the same that I use in reducing the fracture with dorsal displacement, but is applied to the palmar surface instead of to the dorsal.

"In fractures which have been left unreduced for several weeks more power will be required, because the reduction then becomes a refracture. Here it may be necessary to bend the united bone across the surgeon's knee, which is applied to the front of the forearm at the level of the fracture. After the fragments have been broken apart by extension and counter-extension, and a cross-breaking strain over the knee applied to the palmar surface so as to tend to increase the displacement, coaptation is to be accomplished by the manipulation just given for the reduction of recent fractures."

THE EYE AS AN AID IN GENERAL DIAGNOSIS. A Handbook for the Use of Students and General Practitioners. By E. H. Linnell, M.D.  
Philadelphia: The Edwards and Docker Company, 1897.

This book, as the preface expressly states, makes no attempt to describe the symptomatology or differential diagnosis of the various ocular affections which the author describes as indicative of general disease, nor is there any attempt to give the treatment of such affections. The book is divided into three parts. In the first of these we find a brief description of affections of the eyelids, conjunctiva, orbit, sclera, cornea, external ocular muscles, lens, iris, and fundus, which are likely to direct the attention of the physicians to general diagnostic and etiological considerations. Chapter V contains a description of the field of vision and a consideration of some of the visual disorders of intracranial origin. This section of the book concludes with a tabulated statement of general diseases, with more or less characteristic eye symptoms.

The second part of the book deals especially with the so-called reflex neuroses and the relation of ocular affections to functional nervous diseases.

In the third part the toxic amblyopias and the amblyopias caused by various therapeutic agents and poisonous substances are discussed.

The book is similar in its plan to Knies's

well-known work, which, as we learn from the preface, has been fully and freely utilized, although the author's own treatise was in part completed before he had access to the German book on the same subject. It has evidently been Dr. Linnell's intention to avoid technicalities and to make the book acceptable to the general practitioner. The result is a somewhat superficial but fairly interesting *résumé* of the subject.

There are very few illustrations; two of them, showing reversal of the color lines in hysteria, are good. The author has badly mixed the cuts which he has selected from de Schweinitz's "Toxic Amblyopias," four of which appear on page 197. The legends are exactly reversed, so that the fields which represent tobacco amblyopia are described as fields with absolute central scotomas; while those which are the visual fields not of tobacco amblyopia, but of progressive scotomatous atrophy, are given in illustration of the former affection.

### LONDON LETTER.

BY RAYMOND CRAWFORD, M.A. OXON., M.D., M.R.C.P.  
LOND.

Dr. Carr has made a valuable contribution to our knowledge of Non-tubercular Posterior Basic Meningitis in Infants in a paper to the Royal Medico-Chirurgical Society. His observations are based on eleven cases, all of which had come to an autopsy. It will be remembered that Drs. Gee and Barlow previously drew attention to the condition in 1878 in a paper in the St. Bartholomew's Hospital Reports entitled "The Cervical Opisthotonos of Infants," and a further treatise is shortly expected from the joint authorship of Drs. Barlow and Lees. Carr believes the disease to be as common in infants under one year of age as the tubercular form, but very rare above that age. Of the clinical symptoms in his cases, head-retraction was not merely an early symptom but marked and persistent throughout, and of a far more extreme character than is usual in tubercular meningitis. He remarks on the rare occurrence of general convulsions or marked rigidity of the limbs, and ascribes this to the limitation of the disease to the base of the brain. Barlow and Lees, however, have noted the almost constant existence of rigidity of the limbs and usually in

state of extensor spasm. The early appearance and long persistence before death of the state of stupor and semi-coma, due to the increased intracranial pressure as evidenced by the bulging fontanelle, was another point of distinction from the tubercular form, in which the advent of this condition ushers in the end. Carr speaks of the respiration as irregular, sighing, or markedly Cheyne-Stokes in character, while Lees describes it as "cyclical"—*i.e.*, a pause followed by two or three deep sighing respirations. There was no marked irregularity or slowing of the pulse such as is so often seen in tubercular meningitis, and Lees ascribes this latter feature to the vagus not yet having developed its inhibitory power. Vomiting, like head-retraction, was an early symptom and prominent throughout. Squint and nystagmus were occasional, but in nearly all the cases optic neuritis was absent, and this even when the intracranial tension was most excessive. Death was usually by inanition from the vomiting and difficulty in taking food, which in most cases had to be given for prolonged periods by the nasal tube. In the majority of cases death was in from five to eight weeks, but the course sometimes extended over many months, and in some cases seemed to subside into chronic hydrocephalus. There was a great similarity of the post-mortem appearances in all the cases: the essential feature was an inflammatory state of the meninges, not always circumscribed but always most marked at the posterior part of the brain, and leading on to cicatricial adhesions. The thickenings and adhesions in the Sylvian fissure that are usually so marked in tubercular meningitis were generally absent, and when present very slightly marked. In all the cases the lateral and third ventricles and usually the fourth were distended with fluid leading to varying degrees of atrophy of the convolutions. Examination of the thickened membrane at the base of the brain and of the fluid in the ventricles pointed to the absence of tubercle. Carr was disposed to look upon the effusion as dropsical from venous obstruction, with perhaps in some cases an additional inflammatory element, but Lees in the discussion on the paper showed pretty clearly that the fluid was cerebro-spinal, and due to some obstruction in the channels leading from the ventricles, where the fluid was secreted by the choroid plexuses, to the subarachnoid space. Barlow mentioned several cases in which he had found such blockings either at the foramina of Majendie or Monroe, or even

in the spinal meninges at the level of the first and second cervical vertebrae. The question of treatment by drugs is of course closely bound up with the etiology of the disease, while operative procedure must necessarily be based on the post-mortem findings. Carr thinks that injury may in some cases be a predisposing cause, but does not attach much importance to ear disease or to congenital syphilis in its causation. He prefers to look on posterior basic meningitis as a definite disease with a definite—perhaps specific—cause, and draws some analogies with epidemic cerebro-spinal meningitis, which is almost certainly due to a micro-organism. Barlow is also disposed to disregard syphilis, but both he and Lees had frequently noticed a history of catarrh preceding the acute symptoms, and perhaps their starting point. Barlow suggested the middle ear as an intermediary between the fauces and meninges, and mentioned the muco-pus in the middle ear as a convenient nidus for the growth of organisms; he was himself familiar with several cases in which the symptoms appeared to indicate the commencement of posterior meningitis, and which were at once relieved by puncture of the tympanic membrane. Carr considers that the prime aim in treatment should be to subdue the inflammation by counter-irritation, such as mercurial inunction of the throat and neck, an ice-bag to the head, and calomel. Barlow had also found benefit at times from the use of mercurial ointment. No special benefit had accrued either from bromides or iodides. Carr advises puncture of the ventricles when there is great distention, so that if the child does recover, he may recover with a useful brain. This should be slowly drained away through a small trocar and cannula. The danger of operation lies in the too rapid removal of the fluid, as when free exit is given to the fluid the skull is liable to collapse, with fatal results. Barlow had invoked the aid of the surgeon in one case for tapping the fourth ventricle, but though the symptoms are sometimes temporarily relieved there was never any permanent benefit.

The great battle over the University degrees for women has been fought out at Cambridge, and the concession has been refused by a majority of nearly three to one in a very full house. Last year the whole question was referred to a syndicate with a view to effecting some permanent settlement. Shortly stated the position of women students at Cambridge is as follows: They are resident

in colleges of their own in the same sense as male students reside in their colleges within the precincts of the University, and attend the lectures of the University teachers. After conforming to the same laws of residence and educational requirements as the men, they are admitted to the honors examinations of the University. Those who obtain honors are presented with a certificate stating the class in which they were placed, but do not receive any degree. The grievance alleged is that in the judgment of the public the certificate is of inferior value to the degree, and that consequently they are at a disadvantage in competition with graduates of other universities: for this reason they ask to be hall-marked with the magic symbol B.A. The syndicate recommended this concession, at the same time expressly stipulating that the degree should be a mere titular distinction and should carry with it no share in the management of the affairs of the University. On this point the issue was decided, and graduate and non-graduate, resident and non-resident, have risen in holy horror against such a subversion of the existing state of things. We ourselves heartily welcome the result, not because we think that the women have asked too much, but we rather condemn them for asking too little. In very reasonableness the same measure should be meted out, regardless of sex, to two students who have conformed to the same conditions of residence, education, and examination; and on this ground we would decline the compromise which the agitators declared themselves ready to accept as final. The University, however, were alive to the fact that the very illogicality of a degree without a share in the affairs of the University would be a strong vantage ground from which at some future date the male citadel would assuredly be stormed by a generation of agitators under no pledge of peace. The University has been rudely awakened from its dreamy credulity in the singleness of intellectual purpose with which the women students were content to gather up the crumbs that fell from the academic table, to find that after all it had cherished a serpent in its bosom, ready to prey on its very vitals by seizing a share in the management of affairs. Whether the invasion was premature, or whether it failed from tactical maladroitness, the fact remains that women are now further than before from equal rights with men in the University. What is to be the outcome? The women, true to tradition, will not admit their defeat, and are quietly biding their

time against a more favorable season. Some of their male allies meantime are seeking a less remote solution in the formation of a special university for women, under the management of women. This must needs be a costly undertaking even if the university should grow out of some existing institution, and it must needs be many years before such a university could provide the same attractions and facilities as are ready to hand in our old-established universities. We have no belief in the essential mental distinction of the two sexes, and so far from believing it necessary to establish a fresh university to meet their educational requirements, we do not deem it necessary to modify in any way the lines of education as at present laid down.

The medical superintendents of the hospitals of the Metropolitan Asylum's Board have issued a second report on the treatment of diphtheria with antitoxic serum. The report deals with cases belonging to the year 1896, and on the whole confirms the good opinion they had previously formed of the treatment. It cannot be urged against this conclusion that the hospitals have during this period dealt with a milder type of diphtheria, for in those hospitals where the serum treatment has either not been used at all or only in a comparatively small number of cases the percentage of mortality has actually increased. The conclusions which the medical superintendents have arrived at are: (1) that a great reduction has been brought about in the mortality of cases that have come under treatment during the first three days of illness; (2) that the combined general mortality has been reduced below the level attained in any previous year; (3) that the reduction has been most remarkable in the mortality of the laryngeal cases; (4) that there has been a uniform improvement in the results of tracheotomy at each hospital; and (5) that the clinical course of the disease has been beneficially affected.

The Prince of Wales' Hospital Fund has already attained a considerable measure of success, as a sum has been subscribed that will ensure an annual income of not less than twenty thousand pounds, and to this may be safely added a further capital sum of fifty thousand pounds, which should result from the sale of the special Jubilee stamp. In our opinion the difficulties will only commence when the sum has been collected; and it has not yet been shown how far this additional fund will diminish the current income of the hospitals. Who is to have the distribution of

the money? This is a question that is sorely vexing the Charity Organization Society, who have decided to memorialize the Prince of Wales with a view to the formation of a Central Hospital Board with the power of the purse. We are not at all clear that this particular duty would be more satisfactorily discharged by such a body than it has been by the existing governing committees of individual hospitals. This is the view taken by the governors themselves, who for their part have entered a counter-protest against the formation of any outside Board of Control, and ask for the disposition of the fund to be left to a central association of the governors of the hospitals. We are certainly of opinion that the financial management of our large hospitals needs less reform than almost any other branch of their affairs. The evil that above all things needs redress is the multiplication of special hospitals draining off valuable clinical material from the great teaching schools. For this the teaching schools have largely themselves to blame for their tardiness in equipping special departments in a way that would enable them to deal with such special cases.

We would wish to call your attention to the admirable Jubilee number of the *Practitioner*. The number is an abstract and brief chronicle of the advances made in the art of healing during the reign of Queen Victoria. A glance at the names of the contributors will show that no pains have been spared to get the best possible presentation of each subject. The opening sketch by Dr. Samuel Wilks of "Fifty Years Ago" is a fascinating prelude to a series of most instructive articles. Where all are of such high merit it is difficult to particularize, but on the whole we would award the palm to Mr. Treves for his graphic record of "The Progress of Surgery." This Jubilee number cannot fail to be of the highest interest to all who care to reflect on the giant strides with which therapeutics have advanced in the course of the last half century.

---

#### PARIS LETTER.

---

BY A. R. TURNER, M.D. (PARIS).

---

Towards the end of 1896 Dr. Calot, surgeon in charge of the Rothschild Hospital for Tuberculous Children at Berck-sur-mer, a small seaside resort not far from Boulogne, presented to the Academy of Medicine of Paris thirty-seven young patients whom he

had treated for deformation of the spine due to Pott's disease. Dr. Calot, to use his own words, does not hesitate to treat such a case, if recent, like a tuberculous joint which has become ankylosed at a bad angle; he straightens the spine under chloroform.

The method is as follows: Two assistants hold the child over the operating-table, one at the feet, the other at the head; the patient is in a prone position. Besides the two assistants holding the head and feet, another assistant places his hands under the sternum and clavicles, and a fourth assistant under the pubis or even under the umbilical region.

The first two assistants pull strongly upon the parts which they hold, as if to lengthen out the body, and then with the aid of the third and fourth assistants carry upward the two extremities of the rachis, as if to bend it backward. Meanwhile Dr. Calot himself presses with great vigor upon the angular curvature, until the vertebræ which were displaced are level with or even below the others. The hand often perceives, and sometimes the ear, the sound produced by the separation of the two spinal segments and by the vertebræ sliding upon one another. Usually from one to two minutes is sufficient to obtain correction of the deformity.

When the reduction is complete an assistant maintains pressure on the affected region, in order to prevent recurrence, and a circular plaster bandage is placed around the body extending from the head to the pelvis, both inclusive. Dr. Levassort prefers to apply this bandage to the patient while the latter is hung up, head downwards, by the legs.

Over the region where the vertebræ projected a large quantity of cotton-wool is placed, so that the plaster dressing may be drawn tight.

From three to four months after the application of the first dressing it is removed, and the spine will be found almost or quite straight. Another dressing should then be applied, after still further straightening, if necessary. After two or three such dressings the child may be allowed to walk, but with the aid of a corset. Thus from five to ten months have been found sufficient for the correction of the deformity.

In a discussion at the Academy of Medicine on the same subject Dr. Ménard, who is surgeon to the Berck-sur-mer Hospital belonging to the city of Paris, stated that he had three times practised the operation post-mortem in order to examine what were the

anatomical changes produced by it. In two of the cases the deformity was in the dorsal region; in the third in the lumbar region. The spinal cord and the meningeal membranes were not affected by the operation.

In one case an abscess situated in front of the spinal column was torn open, and its contents were thus placed directly in contact with the posterior mediastinum and pleura.

A large opening was caused by the operation in the anterior portion of the spinal column, due to the separation of the two segments of the spine. This opening measured in one case at least eight centimeters in height. It contained remnants of caseous matter, of sequestra, and tuberculous granulations.

Dr. Ménard said that inasmuch as tuberculosis destroyed the bodies of the vertebrae and did not, like osteomyelitis, give rise to any hyperostosis or tendency to the formation of new bone, the vast cavity thus formed would necessarily be filled only by a fibrous cicatrix, which would not have the strength necessary to support the spine and to prevent recurrence of the deformity. Such a cicatrix would likewise be retractile on account of its fibrous nature.

In a discussion at the Society of Surgery Dr. Brun, Dr. Michaux, and Dr. Broca stated that they had all performed the operation several times, with no unfavorable results, and that they had been struck by the ease with which the straightening was obtained. Though of course the final result could not be stated, the immediate result was excellent, and the operation did not appear to be a serious one.

A French medical paper published recently a table giving the number of examinations in medicine passed at each of the seven French faculties of medicine during the school year ending in 1896, and the proportion of rejections. The greatest number of examinations was of course in Paris, amounting to 8955 examinations against 1446, the next greatest number, at Lyons. The smallest number occurred at Nancy, amounting to 406 examinations. One thousand three hundred and nineteen refusals took place in Paris, and only 99 at Lille. It is curious to note the differences between the several faculties in the relative proportion of rejections at various examinations: thus 22.7 per cent. were refused in anatomy in Paris, and 44 per cent., or almost double, in Nancy; on the other hand 14.51 per cent. were refused in Paris in therapeutics, materia medica, hygiene, legal medicine, and pharmacology, and at Nancy only

three per cent. As I have said before, the thesis must be looked upon as a mere formality, for none were refused except in Paris and Lyons—in the first case amounting to 0.33 per cent.; in the second 0.72 per cent., which means that one thesis was rejected at each of those places.

It is worth while noticing how great has been the increase in the number of students at the Faculty of Lyons and the reputation it is acquiring every day, not only as a scientific center, but as a school. Dr. Testut, Professor of Anatomy there, has been appointed editor-in-chief of a series of text-books, destined to serve the student in preparation for his examinations. This will fill a want which has long been felt. There are plenty of large works in French—enormous works, I may say—but nothing of a medium size, nothing which could be thoroughly studied during the necessarily limited time a student has at his disposal.

How frequent it is to find the favorable result of a mercurial treatment given as one of the proofs of the syphilitic nature of some lesion. This axiom, however, has lately been attacked.

At a meeting of the Société Française de Dermatologie et de Syphiligraphie Professor Fournier reported a case in which a patient had consulted him for enormous ulcers of the hand and arm, resembling in all points tuberculous lesions. Not only did the patient deny having had syphilis, but no sign of the latter could be discovered; and even more, the patient was suffering from pulmonary tuberculosis, and the cutaneous lesions dated from many years back.

In order, however, to make doubly sure, a subcutaneous injection of calomel was administered, which gave rise to stomatitis, but which also caused great improvement in the local condition of the patient. A second and a third injection were given, with so much success that only some slight thickening of the skin remained in the region where the ulcers had existed.

Dr. Fournier thought that after all the question should be asked whether calomel did not have a curative action in some varieties of tuberculosis.

In the discussion that followed Dr. Augagneur, of Lyons, spoke of seeing an eighteen-year-old boy suffering from tuberculous lesions of the legs, and who had had a toe amputated for tuberculosis which had lasted about ten years. The administration of potassium iodide caused very great improve-

ment, as it did in another patient suffering from similar lesions.

Dr. Jacquet reported a case in which a recently delivered young woman suffered first from puerperal infection, followed by acute osteomyelitis of the left thigh. The administration of Gibert's syrup caused almost immediate recovery.

Dr. Sabourand stated that the only two known cases of human glanders which had recovered had been taken for syphilis and consequently treated with mercury.

The conclusion to which Professor Fournier came was that mercury and potassium iodide are not reagents of syphilis—that is, an affection favorably affected by them is not necessarily syphilitic.

To the various diseases named above actinomycosis may be added. Only comparatively recently has the favorable influence of potassium iodide in this affection been known, and it cannot be doubted that lesions have been reported as syphilitic because cured by that drug when they were in reality due to actinomycosis.

In a recent communication to the Academy of Sciences Dr. Fouquet, of Cairo, Egypt, said that he had frequently noticed certain curious tattoo-marks on patients consulting him. These tattoo-marks were in the form of lines or dots, were situated on the most differing regions, and did not resemble in any way tattoo-marks intended for ornament.

At first he found some difficulty in ascertaining what was their object. Eventually, however, he discovered that they had been made as a mode of treatment, of revulsion, either against periostitis or chronic inflammation of some articulation or tendon-sheath. In three cases he had seen such tattoo-marks on the epigastric region as a treatment of chronic gastric disturbances; six times he had seen the temples tattooed with a large blue or black spot against chronic headache; and in other cases the knee, the wrist, or the ankles were so marked. The operation is done by women.

Inasmuch as the custom seemed to be more frequent among the Copts Dr. Fouquet was led to believe that it must be of great antiquity, dating from early Egyptian times. This was proved to be so by a curious discovery. In 1891 he examined the mummy of a priestess of Hathor, who had lived at Thebes about 5000 years ago. The mummy was that of a rather young woman, extremely emaciated, the features being drawn and contracted, and the mouth open as in suffering.

The abdomen was sunken and covered with three series of tattoo-marks and scarifications; the first series were already cicatrized.

Dr. Fouquet considered it probable that the priestess had died from an attack of peritonitis, and that the treatment of tattooing had been given for an attack of pelvic peritonitis. Thus 5000 years after death it was possible to make the diagnosis of the cause of death.

The French papers have published an amusing yet sad story of a Polish medical student. Fifty-four years ago he began the study of medicine in Warsaw; lack of means obliged him to act as tutor for twenty years; he passed his first medical examination, but in 1863 took part in the Polish insurrection of that year, and was exiled to Siberia. In 1895 he returned to Warsaw, and has just been received Doctor at the age of seventy-five years. His name is said to be Boryski.

#### *A CASE OF CINCHONISM.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: Denise R., colored, female, aged forty-five, came to my office on Wednesday, May 19, 1897, for treatment. I found her suffering with chronic cervical endometritis, and made a local application of tincture of iodine.

The patient left my office at eleven o'clock, saying that she felt perfectly well and that the pains had completely disappeared. She returned home in a carriage. Her house is one mile from town. At half-past two in the afternoon, coming back from a visit in the country, I inquired how she was, and she told me that she felt perfectly well.

At half-past eight in the evening her husband came to my office and reported that at three o'clock in the afternoon she had had a chill followed by a high fever, and that at the present time she was suffering with a painful stiffness in all the limbs. I prescribed five-grain doses of phenacetine every two hours, and after the second dose she was perfectly easy and slept all night.

Thursday morning at half-past six I visited her and found her without pain but with a temperature of 101° F. The abdominal pains were absent. Supposing that the fever was due to her having been exposed to the hot sun in the middle of the previous day, I prescribed a dose of calomel and podophyllin, a capsule containing sulphate of quinine and acetanilid of each  $3\frac{3}{4}$  grains, and arsenious acid and sulphate of strychnine of each  $\frac{1}{8}$  grain, to be taken every four hours. She

began to take the capsules the same day at ten o'clock.

At eight o'clock in the evening the husband came to me and reported that ten or fifteen minutes after taking each capsule she vomited. I gave her every hour fifteen drops of chloranodyne (P. D. & Co.) and ten grains of subnitrate of bismuth suspended in a teaspoonful of mucilage. After the second dose vomiting ceased and did not recur after taking the capsules every four hours.

Friday morning at seven o'clock I visited her and found her with a normal temperature. She told me that the calomel and podophyllin had acted well and that she was feeling well. Fearing that the fever might return I directed her to continue to take the capsules every four hours, which she did up to two o'clock. At six o'clock, the time when she ought to have taken her capsule, she became delirious and had a nervous attack, during which she bit her arm.

I was sent for, and when I reached the house I found her in the following condition: She was delirious; her limbs were trembling but not rigid; forehead was intensely warm, and when touched seemed to be very sensitive; pupils were contracted; temperature in the axilla was normal; pulse amounted to 80 and respiration to 40 per minute; urine was suppressed since nine o'clock in the morning, the time at which her bowels had moved. I introduced a female catheter and drew about a tablespoonful of a thick, high-colored liquid. Chemical analysis failed to show the presence of any abnormality. Occasionally she recovered consciousness and then complained of an excruciating pain that she located in the forehead, claimed that her sight was dizzy, and that when somebody talked or walked in the room it seemed to her as if there were heavily loaded carts driven around. This sensation was evidently due to exaggerated tinnitus aurium. She complained also of a severe itching all over the body, but examination failed to show any eruption. I applied on each temple a fly-blisters of the size of a dollar and gave her fifteen grains each of bromide of potassium and hydrate of chloral dissolved in camphor water every hour. After the second dose she went to sleep and slept until three o'clock Saturday morning.

At that time she awoke and called for a little water. After having taken a sip of it she began to vomit, and the vomiting was persistent. I was sent for and reached the house at half-past four. She was still vomiting, and I gave

her a hypodermic injection of one-fourth of a grain of morphine. Vomiting ceased at once, and she slept till twelve o'clock. When she woke up the pain in the head had disappeared, and the patient was feeling well.

Sunday morning I visited her and found her well, without fever and without pain. She reported that she did not feel any more the pain in the uterine region she experienced before the application of iodine.

According to my view of the case the patient had been suffering from cerebral congestion due to the toxic action of quinine, and as she had not taken any more of the drug than I am used to give without bad effect to all my patients having fever, I concluded that I was in presence of a case of cinchonism arising from idiosyncrasy of the patient. I inquired about her and discovered that when she was thirteen years old a certain dose of quinine the amount of which she could not determine had made her delirious for six days, and that three or four years ago a ten-grain dose of the same drug had produced the same effect for twenty-four hours. Moreover she told me that her son had the same idiosyncrasy, and that a few years ago after having taken some quinine he had had nervous attacks, delirium, and unconsciousness.

I report this case as being a curious manifestation of toxic action of therapeutical doses of quinine. In my practice I have seen cases of idiosyncrasy accompanied with urticarial eruption and cyanosis, but never with cerebral troubles as in the case which is the subject of this report.

PIERRE SILLAN, B.S., Ph.M., M.D.

ST. MARTINVILLE, LA.

#### COMPOUND COMMINUTED FRACTURE OF TIBIA AND FIBULA.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: The following case is of interest as showing the results of conservative treatment in an injury commonly regarded as demanding immediate amputation:

March 2, 1897, at 1 P.M., Mr. Wm. Young, aged twenty-five, was run over by an empty "gondola" freight-car, one wheel passing over the right leg about two inches above the ankle (the flange of the wheel nearest the ankle), causing a simple fracture of the tibia about the middle of the leg and a compound comminuted fracture at the point of contact of the wheel above and the rail below. The fibula was also broken about the same place.

On first sight there seemed to be no favorable signs looking toward saving the limb, but while washing and cleansing the wounds we noticed that the circulation in the anterior tibial artery was good, also that there was some weak pulsations in the posterior tibial vessel. Some oozing of blood from an open skin wound over the tendo Achillis about four inches above the ankle seemed to indicate a rupture of blood-vessels, although not sufficient to require any active intervention. The skin was also broken over the tibia at two other places where the wheel came in contact with it.

The leg was washed with bichloride solution 1:2000, after which the wounds were dressed with iodoform gauze, were well covered with powdered iodoform, and the leg was placed in a Levis metallic splint well padded with absorbent cotton. There was no difficulty in securing and maintaining reduction, except that the upper end of the lower fragment of the tibia exhibited a tendency to forward displacement, which was very easily corrected by a spring such as is used to hold the trousers of a bicycle rider from the wheel.

After the dressing was completed Dr. Goeben and myself, after taking into consideration the good circulation, the almost perfect sense of feeling in the foot, and the ability of the patient to move his toes, concluded to state the case to the patient and let him decide as to the advisability of an attempt to save the limb. We told him that the chances of saving the limb were very small indeed, and that the risk of losing his life in the attempt was so much greater than after an amputation that we did not think it advisable. This risk he, however, consented to take. He rested well, requiring a few doses of morphine the first two or three nights; had very little fever, never over  $101^{\circ}$ ; his appetite was good, bowels regular, urine at first concentrated and feverish.

March 4, on account of oozing, the dressing was changed and an opening made in the splint over the wounds to allow of free drainage. The skin over the tibia became black and gangrenous for about two square inches, but sloughed in a week or ten days, leaving a clean, healthy-looking granulating surface which secreted very little pus and under a dry dressing of iodoform and powdered boric acid gradually healed over until at present there is only a small spot less than an inch square not healed. There is good union of the fibula, and the tibia is becoming firm, with the prospects of a good and useful limb.

The unfavorable prognosis of such cases as expressed by reporters in *Stemen's Railway Surgery* lead me to report this case, as illustrating the recuperative powers which are manifested sometimes under most unfavorable circumstances, entirely setting at naught surgical rules, and impressing the importance of individualizing cases after thorough and painstaking investigation.

There was no doubt about the car running over the leg, as two persons also saw the wheel pass over the leg.

The car weighed 19,400 pounds.

DAVID GARDNER, M.D.

LEHIGH, I. T.

#### A SIMPLE METHOD OF PRESERVING CULTURE MEDIA.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: For several years I have found it very difficult to profit by the excellent advice received during my college course in bacteriology, for several reasons, the principal of which was the difficulty in obtaining culture media at the time needed. Being remote from any laboratory or source of supply for such articles, it was necessary that I should make it myself or do without. If I prepared a quantity during a quiet time in my practise the chances were that it would be dried up and unfit for use by the time I most needed it. I tried rubber caps and sealing the tubes, but these methods, like all other suggestions tried, failed to give the satisfaction sought; besides in some cases adding considerably to the expense of the preparation.

At last I tried the following method, which is so simple and proved so perfectly successful that I resolved to give it to my fellow practitioners:

During a season of the year when I can expect to have the time I prepare a quantity of tubes ready for inoculation of all the different varieties of media used. I then take ordinary glass Mason fruit-jars, put a little cotton or a cloth in the bottom, with an inch and a half or two inches of some disinfectant solution, such as carbolized water; the can is then filled with the prepared tubes and sealed with the screw-top and rubber, as in canning fruit, and set away for future use—preferably in the cellar. By this method I have always a supply of culture media on hand, ready for use at any time of the year.

Yours truly,

E. E. SIMPSON, M.D.

### THE CHOICE OF THE VARIOUS PREPARATIONS OF DIGITALIS.

By H. A. HARE, M.D.,

Professor of Therapeutics in the Jefferson Medical College of Philadelphia.

For many years members of the medical profession have been wont to regard the various pharmaceutical preparations of digitalis as possessed of a widely different physiological effect, far exceeding the variation naturally arising from the relative strength of an infusion as compared to a tincture. In other words, it has been generally conceded that no

dose, large or small, of the infusion could be hit upon which would produce effects caused by any given dose of the tincture; or to express it still more clearly, it has been the general view that each of these preparations was capable of producing effects peculiar in some respects to itself. It has been supposed that this variation depends upon the relative proportions of the various active principles of digitalis held in solution by the water or alcohol with which the preparation is made, and if it be true that each preparation has an effect of its own it is also undoubtedly true that this is due to the reasons just suggested, as I am about to point out.

It will be recalled that digitalis contains at

least five principles, of which four are physiologically active and the fifth inactive. From these there may be developed other substances by chemical alterations or decomposition, but they probably are not primarily present. Each of these ingredients possesses a physiological action of its own, and each has a solubility of its own. Of the four active constituents, digitalin, digitoxin, and digitalein act upon the heart muscle, while digitonin has an entirely different effect, namely, the power of depressing the vagus nerves centrally and peripherally and the inhibitory ganglia in the heart. The digitalin here referred to is not the digitalin of amorphous form prepared according to the process of Homolle, nor the crystalline digitalin of Nativelle, neither of which is a pure digitalin, but it is the digitalin of Schmiedeberg.

The effect of Schmiedeberg's digitalin upon the heart is that of a powerful stimulant, for under its influence the individual heart-beats become more powerful (four to six times greater than normal) and it simultaneously causes a rise of blood pressure, first by increasing the strength of the heart, and second by stimulating the centric and peripheral vaso-motor apparatus.

The physiological effects of digitalein and digitoxin are identical with those of digitalin except that they do not stimulate the vaso-motor center, nor the pneumogastric apparatus, and so do not directly raise blood-pressure or slow the heart. In other words they increase the force of ventricular contraction. The effect of digitonin being to depress the vagus nerves, it will be seen at once that it antagonizes the vagal effect of the digitalin on these fibers and so prevents digitalis from slowing the heart to the extent that would result from the use of digitalin alone. It also depresses the heart muscle. The proportion of digitonin in digitalis varies, but it is not present in sufficient amount to entirely overcome the inhibitory influence of the digitalin.

If we now turn to a consideration of the solubilities of these principles we can readily explain the different effects produced by the infusion and tincture or fluid extract. Digitonin is soluble in water, as is digitalein, but digitalin is only slightly soluble and digitoxin is scarcely soluble in water at all. As a result the use of the infusion in a case of heart disease would not give the patient the same degree of cardiac power as the use of the tincture, for not only would the most powerful stimulant of all to the heart, vaso-motor system, and vagi be present in small

amount, but in addition the large proportion of digitonin would antidote it.

On the other hand, digitonin is sparingly soluble in alcohol, while digitalin and digitalein are readily soluble in it, digitoxin being slightly so. It would seem therefore that in the presence of a failing heart and circulation the tincture or the fluid extract are the preparations greatly to be preferred to the infusion, because they contain large amounts of the active stimulant ingredients.

The reason that the infusion acts efficiently in some cases as a diuretic probably depends upon the fact that as it does not contain so much digitalin it is less apt to cause spasm of the renal vessels, but if the heart is feeble and there is renal stasis, the tincture is probably the better preparation to overcome this state, because it both aids the heart and by contracting the renal vessels overcomes the stasis. The use of digitalin is inadvisable unless we are sure that we get that made according to the process of Schmiedeberg, for the other digitalins usually sold are very uncertain. The infusion is far more apt to disorder the stomach than the fluid extract or tincture, because of the irritating digitonin.

#### *MASTOID EMPYEMA WITHOUT THE USUAL OBJECTIVE SYMPTOMS.\**

---

BY S. MACCUEEN SMITH, M.D.,

Clinical Professor of Otolaryngology, Jefferson Medical College;  
Surgeon in Charge Ear, Throat and Nose Department, Germantown Hospital, Philadelphia.

---

My object in presenting a paper on mastoid disease is not in any degree an attempt to treat the subject in an exhaustive manner, but chiefly to consider a variety of the disease not frequently encountered. Neither shall I burden you with any lengthy histories, but will briefly cite a few illustrative cases, and confine my remarks to the statement of such facts as seem necessary to elucidate the chief points of interest.

As this and other aural affections can not, from their clinical aspects, be recognized and treated strictly in accordance with prescribed rules, it would seem that a large clinical experience, together with mature judgment, and bold, yet conservative methods of treatment, will continue to characterize the future notable advances in *surgical otology*,

---

\*A paper read before the Section of Laryngology, Rhinology and Otolaryngology of the American Medical Association, June, 1897.

just as similar methods have so largely contributed to the modern achievements of general surgery. It is quite true that certain well defined symptoms and appearances are commonly found in, and are somewhat diagnostic of, the usual form of mastoid disease. Nevertheless, when we consider the numerous exceptions to this rule, we are constrained to the belief that while general rules are of much value and applicable to most patients, yet their recognition and application in obscure cases is not only confusing, but positively misleading. For example, let us consider the large number of mastoid operations performed, when the only justifiable symptoms for such a procedure are swelling, redness and tenderness, or pain on pressure over the process; whereas these local manifestations were clearly secondary and incident to an existing circumscribed inflammation within the external auditory canal. On the other hand, because of the absence of such symptoms, an existing mastoid empyema may not be recognized or even suspected, although an examination of the external canal would have revealed distinct tumefaction or bulging of its postero-superior quadrant, a condition that is distinctly diagnostic of serious mastoid disease even when no previous tympanic inflammation has existed; and especially if accompanied by considerable head pain, tinnitus, and vertigo.

The temperature and pulse in these cases are often unreliable, although of considerable importance when associated with other definite symptoms. In one case that came under observation in which the ultra-conservative or expectant line of treatment had been followed (the only symptoms being head pains and otorrhea), little or no variation in either temperature or pulse was noticed until six hours preceding death, when it suddenly registered  $108\frac{1}{2}^{\circ}$ . The post-mortem revealed extensive necrosis of the mastoid and petrous portions of the temporal bone, all of which resulted from an acute suppurative otitis media.

I am not quite certain but that the symptoms to which I wish in particular to call your attention may only add one more to the already numerous doubtful diagnostic indications. The several patients who have done me the courtesy to present themselves this afternoon for your examination can in all probability establish what virtue there may be in this local manifestation much better than any explanation I might make.

Within a comparatively brief period it has

fallen to my lot to see and operate upon some nine cases of mastoid empyema, in none of which were the usual mastoid symptoms present, but in all the pain (being intense in three) was confined to the *occipital* region, the chief point of intensity being situated immediately below and slightly anterior to the angle formed by the junction of the inferior curved line with the external occipital; or a line drawn one inch below the external occipital protuberance, and one inch anterior to its (the line) inferior extremity will indicate the point of election. In all of these cases the pain seemed to be unusually severe, and notwithstanding some aural suffering may have been experienced at the beginning of the attack, it promptly subsided in the ear and became constant and increasingly severe at the point designated. In this entire series of cases the *occipital pain* was of such commanding and urgent importance that other symptoms failed to attract the attention of either physician or patient. In each and every case opening the mastoid evacuated a quantity of pus more or less offensive, which in turn relieved the suffering, otorrhea, or other symptoms.

I will now ask your attention to the consideration of several rather typical cases illustrative of this unusual form of mastoid disease.

CASE I.—W. R. C., aged nine years, suffered from an attack of measles on February 1st, 1896, followed four days later by a severe pain in the left ear. At the end of one week a spontaneous rupture of the membrana tympani occurred, which, however, only gave slight relief. Three days later, notwithstanding the copious discharge, the pain grew worse. After some days of suffering Dr. E. E. Graham was consulted, who the following day requested an examination by the writer. We found an ample opening situated in the posterior inferior quadrant of the membrana tympani, through which escaped a free discharge. The pain, being intermittent in character, was not then referred to the ear or mastoid, but to the *occipital* region; neither was there redness or swelling over the mastoid, nor could pain be produced by pressure over the process, but possibly a "doubtful tenderness" was experienced on *deep* pressure over the antrum. There was an entire absence of tumefaction of the postero-superior wall of the external canal.

If in an acute suppurative otitis media pain persists after free drainage has been established, it must be due either to exten-

sive maceration of the mucous lining of the tympanum, or to a suppurative involvement of the mastoid, even if the usual external signs of mastoid empyema are absent. We can exclude the former if under favorable circumstances pain continues more than a few days (in this case it had extended over several weeks); whereas in the latter *continuous* suffering following an acute ear disease with active suppuration would only confirm the supposition of mastoid empyema, especially when there is added to this the presence of *occipital* pain, which we are almost prepared to believe diagnostic in such cases.

The mastoid was opened April 15, or about five weeks after the ear complications began. As soon as the antrum was reached a large quantity of pus escaped, the opening communicating freely with the external canal. After proper irrigation the wound was packed with iodoform gauze, which was renewed at stated intervals. From the very day of operation all suffering ceased. Three weeks later the mastoid wound had entirely healed, the discharge had ceased, and the hearing had resumed its normal condition, which improvement you will notice continues to-day, sixteen months after the date of operation.

CASE II.—J. C. W., aged 39 years, received a punctured wound of left thumb in January, 1895, which at once became very painful. Two days later the glands of the left side of neck became painfully swollen; pus formations occurring two days later, at which time the same were evacuated. Six weeks later similar abscesses were opened, both on the neck and right leg. About ten days subsequently two additional abscesses were opened on the left leg and one on the left arm.

The general pyemia lasted about ten weeks, the patient being delirious a part of this time. One year after receiving the punctured wound he consulted the writer at the suggestion of his physician, Dr. A. H. Hulshizer. At this time his head pains continued to be severe, being confined to the left side, especially marked over the *occipital* region. Objectively the mastoid was utterly devoid of localizing symptoms, although marked hyperemia and bulging of the left membrana tympani were present. A free incision of the drum-head liberated considerable pus; the *occipital* pain, however, continued.

On March 19, 1896 (or about two months after consultation), we opened the mastoid. The cells were necrotic and well filled with thick brownish-yellow pus. As the antrum

and attic were extensively involved in the necrotic changes, we continued the operation into the middle ear, establishing direct communication between the external auditory canal and the opening in the mastoid. The usual after-treatment was carried out. The patient was relieved of all suffering, and made a slow but uninterrupted recovery; his loss of hearing was quickly recovered, and to-day, you will observe, remains quite normal.

CASE III.—Mr. M. A. J., aged twenty-eight years, contracted an attack of la grippe, in November, 1895. The usual febrile and catarrhal symptoms continued for about ten days, when the left ear became involved. The pain from the acute otitis media continued for five days, at which time the membrana tympani ruptured, relieving the pain only slightly. Under treatment this discharge ceased in two weeks, which, however, only served to increase the suffering. This cessation of discharge and continuation of pain lasted for about five weeks, when an acute recurrent otitis media developed, causing extreme suffering for two days, when the membrana tympani again ruptured, relieving the patient somewhat. The discharge from the ear and pain over the left side of head, especially severe over the *occipital* region, continued for one month longer, when he consulted Dr. J. C. Wilson, who in turn referred him to the writer on February 27, 1896. He did not show any of the usual symptoms of mastoid disease; not the slightest redness, swelling, nor tenderness on deep pressure; but the *occipital* pain was and had been a prominent symptom.

A large quantity of granulation tissue filled the tympanic cavity, and extended into the external canal for about one-eighth of an inch. This obstruction to free drainage was, we thought, quite sufficient to account for his suffering. On March 9, under general anesthesia, we removed from the tympanum this entire mass of inflammatory products, no ossicles being found. Some relief was obtained for three days, at which time the pain became quite as severe as ever. On March 16 (seven days later) we opened the mastoid with little or no difficulty, the bone having become very soft from extensive necrotic changes. The mastoid antrum communicated freely with the external canal, thus greatly facilitating the usual after-treatment of irrigation, etc. On account of the unusual necrotic changes, we made the opening into the mastoid permanent for a period of eight months, at which

time he had entirely recovered, except that the lost hearing was not regained. In this patient (as has been noted in several similar cases) the suffering was permanently relieved from the date of operation, the prompt cessation of the *occipital* pain being especially marked.

CASE IV.—R. A. M., aged forty-seven years, suffered from a severe attack of follicular tonsillitis in October, 1894. About one week later he developed a painful otitis media of left ear. He claims that the acute suffering continued to grow progressively worse for a period of two weeks, at which time he consulted Dr. Noell, of the Cooper Hospital, Camden, N. J., by whom he was referred to the writer at the Jefferson College Hospital. An examination showed moderate congestion of the inferior membrana tympani, the membrana flaccida being *intensely* inflamed. There was no bulging of any part of the membrane. The malleus could be distinctly outlined in its entirety. There was neither pain, swelling, nor redness over the mastoid. The suffering was referred chiefly to the *occiput* and left posterior side of the head. Not being able to account for his unusually severe suffering, we referred him to Dr. F. X. Dercum, who reported negative results from a neurologic point of view. The ophthalmic report was likewise negative.

For some time he had been treated in various ways for "neuralgia," but the administration of morphine alone gave relief; this being effective only while under its immediate influence. He was admitted to the hospital, and under general anesthesia we freely incised the inflamed membrana tympani, but did not find any fluid. His suffering was somewhat relieved for five days, when the *occipital* pain returned with increased vigor, the incised drum-head having healed in the meantime. On November 1st, 1894, we opened the mastoid, and were gratified to see a quantity of pus flow from the process. This evacuation of pus naturally relieved the suffering, and he made an uninterrupted recovery. Furthermore, his hearing is normal, in which condition it has continued for more than two years.

In conclusion we may add:

That the history of these cases reveals an entire absence of the *usual* objective symptoms attributed to mastoid empyema.

That redness, swelling and tenderness over the mastoid region are not necessarily diagnostic of deep mastoid disease, but are frequently secondary local manifestations of a

furunculous inflammation of the external auditory canal.

That tumefaction or bulging of the postero-superior quadrant of the external canal, especially when accompanied by otorrhea, is always diagnostic of mastoid empyema (even though all local manifestations are absent) and demands prompt surgical interference.

That a consideration of the pulse and temperature are necessary and of much value in some cases, while in others they are totally unreliable, even misleading and confusing.

That in otherwise more or less obscure cases the presence of *occipital* pain (as above detailed) is of commanding diagnostic importance.

#### THE TREATMENT OF LUPUS.

BY BALMANNO SQUIRE, M.B. LOND.,  
Surgeon to the British Hospital for Diseases of the Skin,  
King's Cross, London.

The author describes a new mode of treating lupus. This is an endeavor to improve on the methods devised by Professor Volkmann of Halle for the treatment of this disease. Volkmann's methods were of two kinds: the one was the scraping out of the soft and friable new formation by means of comparatively sharp spoons; the other was the execution of a multiplicity of closely placed but shallow punctures, made with the point of a lancet, this latter process being designed for the treatment of such portions of the diseased area as are not sufficiently soft and friable to yield readily to scraping. Mr. Squire states that these methods, although always leading to rapid and considerable temporary improvement, never induce a complete arrest of the progress of the disease. After reviewing various other methods of treatment, such as excision, the actual cautery, the thermo-cautery, chemical caustics, and the various modifications of puncturation, and explaining what he regards as prohibitive disadvantages in the case of each of these, he assigns reasons for objecting also to the administration of either chloroform or ether in operating on lupus. He accordingly avails himself of local anesthesia, namely, by freezing the affected area by means of Richardson's apparatus. This preliminary is indeed an essential condition, in more ways than one, of the method which Mr. Squire has devised, since for the performance of his operation a glacial state of the affected area is indispensable. In this state, as he finds, the skin can be carved, or as he expresses it "sculpted," with the same

ease as if it were moderately hardened putty, and the diseased structure can thus be brought away in solid chips. For executing the "sculpting" he uses a modification of Volkmann's steel spoons, that is to say, spoons of about one-fourth the size of Volkmann's and having much sharper edges. In the glacial state, sound skin and diseased skin comes away with equal facility under the action of these spoons. Accordingly Mr. Squire finds himself able by means of them to remove not only the soft and friable tissue which alone comes away under the customary method of scraping as devised by Volkmann, but also the whole of such tougher portions of skin as are in a less degree affected with lupus. But not only is he able thus to remove the whole of the area which may be in any degree diseased, but also a zone of apparently perfectly healthy skin. The last he considers it specially necessary to remove since he holds that the real limits of a lupus patch extend for some little distance beyond its visible limits.

He claims for his operation not only that it is more thorough, but also that much more precision can be imparted to it than is possible in the operation of "scraping." He describes his operation as a "specially conservative excision of lupus, executed not with a knife but with a curette, and performed under conditions which permit of more than customary precision." A necessary feature of this method is that the limits of the patch to be "sculpted" must be previously carefully marked out with a black line drawn round it on the skin. This is requisite because when the skin is frozen the lupus-patch and the skin around it are alike of a uniform dull white color, so that all trace of the margin of the patch disappears for the time being.

Mr. Squire draws attention to the fact that the operation he has devised is essentially different from Volkmann's operation (scraping) not only in detail but in scope. He claims other advantages than those above referred to as incidental to operating on skin in the glacial state. One of these is that not a single drop of blood escapes to embarrass the operator; this he regards as an important factor in an operation which, from his point of view, demands considerable precision for the attainment of a successful issue. Another is that in the glacial state the skin is absolutely rigid. In Mr. Squire's view this circumstance is a notable additional aid to the attainment of precision. In the operation of scraping, as ordinarily performed, an em-

barrassment arises from the ready yielding of the skin in whatever direction the curette may at the moment be pressed. "The considerable elasticity of the skin and its loose attachment to subjacent structures renders the 'scraping' of a lupus-patch as ordinarily performed a very imperfect procedure; whereas the frozen skin around the frozen patch fixes the patch all round as firmly as a drum fixes a drum head. Another advantage claimed is that the frozen skin does not clog the curette."

After thus thoroughly carving out from the frozen skin all of the diseased structure so far as ascertainable, Mr. Squire "still further safeguards" the efficacy of his operation by "linearly scarifying" the floor and margin of the sculpted-out area at a subsequent sitting by means of his "multiple linear scarifier." This is an instrument composed of sixteen parallel scalpel-blades fixed on one handle, the cutting edge of each blade being separated from that of its neighbor by an interval of only a thirty-second of an inch. For this operation the area is again frozen as before. He says: "By such means I have succeeded in completely healing very many cases of lupus, in such wise that the patients have remained absolutely free from the disease for a series of years." In conclusion he desires to say that he has acquired practical experience of a great many modes of treating lupus, but no method that he has tried has yielded him results so good as the one he has here described.

---

#### *THE TREATMENT OF HEMORRHOIDS BY THE INJECTION METHOD.*

BY LEWIS H. ADLER, JR., M.D.,

Professor of Diseases of the Rectum, Philadelphia Polyclinic and College for Graduates in Medicine; Surgeon to the Charity Hospital, and to the Out-patient Department of the Episcopal Hospital; Professor to the Professor of Anatomy, Medical Department University of Pennsylvania, Philadelphia, Penn.

---

I am sure that my experience in rectal work is by no means unique, in that the majority of patients with hemorrhoidal troubles come to me greatly prejudiced against any operative procedure involving the employment of general anesthesia, and especially the use of the knife. These objections have been raised not only by the laity but also by physicians who have been similarly affected. Such an argument should not and would not prove a factor in altering the character of

advice to be given to a patient were I satisfied that only one plan of treatment could effect a cure; but where a choice exists of several methods of effecting the same or similar results, it is not only our duty but a necessity for us to respect the patient's wishes.

In a number of instances, sufficient to convince me of the efficiency of the method and to enable me to place my opinion on record, I have treated internal hemorrhoids (in selected cases only) by the injection of carbolic acid. The results obtained in every instance have been eminently satisfactory to patient and myself alike.

I am thoroughly acquainted with the unsatisfactory experiences and the unfavorable opinions expressed regarding this treatment by such authorities as Kelsey of New York, Mathews of Louisville, Ky., Allingham of London, and others of equal eminence, and I am furthermore free to confess that for a long time the weight of this testimony deterred me from giving the method a trial. On the other hand, I have diligently perused the literature, past and present, dealing with the other phase of the question, and after reading the excellent treatise on "Hemorrhoids and other Non-malignant Diseases of the Rectum" by W. D. Agnew, M.D., of San Francisco, California, I determined to test the merits of the treatment.

*External Hemorrhoids.*—Agnew\* admits that the quickest, neatest, least painful and most desirable way of disposing of any form of external hemorrhoid, cutaneous tag, or like redundant tissue is by excision, but employs the carbolic acid injection in those cases in which the patient is averse to being treated by any plan involving the use of the knife or scissors. He claims that this method effects a cure, to which such persons will readily submit, although informed that a longer time is required for the complete eradication of a tumor thus treated, and that more pain and inconvenience may be experienced from the effects of the operation than would result from that by excision. Personally, I have had no experience with this method of treating external hemorrhoids, preferring and always advising in operative cases the excision of such tumors.

According to the same authority† and as the result of his observations, the objections to the treatment of external hemorrhoids by

carbolic acid injection pertain solely to the length of time required for the removal of the tumor—a period of three or four days—and the pain following the injection, which is not intense, but is at times more or less annoying, usually beginning within one or two hours after the operation, and continuing for twelve or fourteen. Agnew advises against the employment of this method in the treatment of external hemorrhoids when inflamed and in a highly sensitive state. He especially notes the care that should be taken when operating on these tumors by injection, to see that quite a considerable portion of the cutaneous surface, especially at the summit of the pile, is affected by the solution applied just beneath the skin; otherwise the skin will become inflamed in order to let out the interior coagulum, which he has often seen come out in three days without suppuration or showing the appearance of much moisture, and in one unbroken cystic-looking mass. The operation is to be performed with a view of cauterizing all of the tissue to be removed, which can be governed only by the dictates of judgment and as a result of experience.

*Internal Hemorrhoids.*—It is to the treatment of internal hemorrhoids by the injection of carbolic acid that I wish especially to invite your attention, in the hope of eliciting a free discussion as to its merits or demerits based upon the actual experiences of those who have given the method a fair trial.

*Formula.*—The formula which I use is the one advocated by Agnew, and the method of its preparation is best detailed by a *verbatim* description as given in Dr. Agnew's work on Diseases of the Rectum.\*

"The solution of carbolic acid found to be uniformly successful in the treatment of hemorrhoids is prepared by first making a solution of the acetate of lead and borax in glycerin, in the proportion of two drachms each of the chemically pure salts to one ounce of Price's glycerin.

℞ Plumbi acetat.,  
Sodii biborat., āā ʒij;  
Glycerinæ, fʒj.

Mix in a graduate, pour into a two-ounce vial, and let it stand for twenty-four hours.

"The solution of the salts is hastened by placing the vial in a warm-water bath and allowing it to remain there for fifteen or twenty minutes. The glycerin can be handled to a better advantage, and its measurements

\* *Op. citato*, p. 18.

† *Op. citato*, pp. 22-23-24.

\* *Op. citato*, pp. 35 and 36.

more accurately made and retained by warming it as well as the graduate before it has been poured into the graduate and the chemicals have been added.

"Select Calvert's No. 1 crystallized carbolic acid and pour a sufficient quantity, liquefied by warmth, into a two ounce graduate to measure one ounce, and add two drachms of distilled water. To this add enough of the glyceride of lead and borax previously made to make the combination measure exactly two ounces.

℞ Acidi carbolici (cryst.), 3j;  
Aque distillat., f 3ij;  
Sodii biborat. et plumbi acetat. et glycerin, f 3vj.  
Misce et sig.: Solution for hemorrhoids.

"The object of the water in the formula is to lessen the syrup-like consistency of the preparation. Should equal parts of crystallized carbolic acid and the glyceride of lead and borax be combined, the solution will be found rather too heavy for convenience. It will not flow through the hemorrhoidal needle as freely, nor take hold of the tissues when injected as quickly, as does a solution containing a small proportion of water.

"Be particular in the weights and measurements, and the purity of the ingredients entering into this preparation, as anything unnecessarily irritating should be scrupulously avoided. I have tried synthetic carbolic acid and found the odor of tar to be decidedly stronger, and believe it much more acrid and irritating than the commoner preparations; neither can I see that anything is gained in using vegetable glycerin.

"Some make no allowance, in attempting to give the formula, for the increase in bulk of the glycerin occasioned by the addition of the one-half ounce of solids, and direct that the ounce of carbolic acid be added to the full amount of the glyceride of lead and borax when made. By this inadvertence not much over a thirty-five per cent. solution of carbolic acid is obtained. After trying the acid in varying strengths and watching its effects, I have concluded that not less than a fifty per cent. solution should be used. The addition to the solution of the acetate of lead is designed to restrict the action, and that of the borax to lessen the irritative properties of the acid. The acetate of lead not only keeps within limit the distribution of the acid at the time the solution is forced out of the hypodermic syringe, but of itself combines with a certain portion of the albumen of the blood and other tissues, forming the albuminate of lead. If I were to make a change in

the formula it would be toward an increase rather than a diminution of the quantity of acid."

*Preparatory Treatment.*—This includes a careful study of the patient's physical condition. I would advise against the employment of the injection treatment in cases predisposed to phthisis, or already affected by this disease, and in diabetes or in chronic diseases of the liver, heart, or kidneys.

During an acute inflammatory attack of hemorrhoids is not a favorable time to operate, on account of the engorged condition of the rectal vessels and the irritability of the mucous membrane of the bowel. Such conditions should be relieved by local medication and by remedies directed towards regulating the bowels and increasing the activity of the liver.

*Operation.*—At the time of the operation the hemorrhoids are exposed by inducing the patient to have a stool or to sit over hot water.

It is advisable to smear vaselin over the muco-cutaneous surfaces prior to operating, as advised by Agnew,\* in order to prevent the solution used for the injection coming in contact with the parts.

The patient should be placed in Sim's position, and the hemorrhoid being sufficiently well exposed it is to be punctured at its most accessible point, preferably about midway between its base and apex, and the point of the needle passed to about the center of the growth. Care must be exercised that the needle's point is inserted beyond the proximal end of its opening, as otherwise the preparation will be injected on the outside of the tumor. In a large growth eight or ten punctures may be found necessary.

The injection is to be inserted slowly, several drops at first, then drop by drop, watching the action of the solution as shown by the change of color that creeps over the surface of the pile. This change of color Agnew states is quite marked with hemorrhoids of a delicate covering, less so with those possessed of more fibrous coats. The needle should be held in position for a short time, and if the quantity injected appears to be less than needed, more of the solution should be used. Agnew states that the solution takes effect slowly by virtue of its astringency and syrup-like consistency, and no doubt extends farther than is always apparent at the time of operating. If the hemorrhoid be large, and its cavities filled with blood exhibiting strong

\**Op. citato*, p. 34.

arterial pressure, more time will be occupied in performing the operation than is generally supposed, as many as twenty or thirty minutes occasionally being required. The time is taken up in such cases by holding the needle in place until assured that sufficient of the solution has been used to effect the desired result. If the part feels doughy or springs up under the finger like an elastic ball when pressed, or blood flows freely through the place of puncture after the needle has been withdrawn, either enough time has not been allowed for the preparation to take full effect, or a sufficient quantity has not been injected.

After the entire cavity of the tumor has been thoroughly reached by the injection, and in a large tumor a few drops have been deposited on the surface of the pile so as to be sure of thoroughly cauterizing the more dense tissue of its integument—which Agnew states might otherwise inflame, creating unnecessary pain and suffering—the hemorrhoid is to be thoroughly dried, covered with carbolyzed vaseline, and returned within the bowel. Several tumors may be treated in this manner at one operation, and I have seen no bad results ensue, although I have used several drachms of the solution in a single treatment.

No speculum is required as a rule in this method of treating hemorrhoids.

The needle required for the hypodermic syringe employed in giving these injections should have a little larger bore than the needle employed for ordinary hypodermic use, so as to permit the fluid to flow through readily, which the smaller needle prevents, owing to the consistency of the injection fluid.

*After Effects and Treatment Following Operation.*—In some cases pain is experienced several hours after the operation, but is usually controlled by suppositories of the aqueous extract of opium, one-quarter of a grain, and the extract of belladonna, one-eighth of a grain, used *pro re nata*. Difficulty in urinating may occur, and is usually relieved by a hot-water bag applied above the pubes, or by a sitz bath. Catheterization is seldom required. A desire to have the bowels moved can be allayed by the suppositories and by hot-water compresses applied to the anus.

I do not endeavor to confine the bowels for any definite period after this operation; usually the patient's fear of having a movement effectually restrains such a desire, and on the third day I am in the habit of ordering administered fractional doses of calomel

and soda followed by a saline. Just preceding the time the bowels act I order given a rectal injection of eight ounces of carbolyzed oil (two per cent. carbolic acid) or an injection of slippery elm tea or of borax water (a dessertspoonful of borax to the pint of water).

A peculiar odor, sometimes noted when the coagulum is being thrown off, should not be interpreted as indicating suppuration.

Agnew states that to effect a safe, speedy, and radical cure of a case of hemorrhoids it is desirable to get rid of the tumor bodily, not by shrinkage or contraction, leaving a hard or indurated prominence, subject to resuscitation and a return of the old malady, nor by inflammatory destruction, but by a separation of the spongy and vascular growth from the normal tissue of the body, the same as if it were dissected from its remotest attachments. This is obtained by putting a sufficient quantity of the preparation recommended just where it is required and such results will invariably follow.

My experience with the treatment thus far leads me to endorse most heartily Dr. Agnew's strong commendation of the method which he has so successfully employed for a long time.

Personally, I cannot speak authoritatively regarding the permanency of the cure effected by the carbolic acid injection of hemorrhoids, for I have not had an opportunity of observing cases treated by this method for a longer period than two years, but from my observations I am inclined to believe that it is a radical procedure.

Regarding the dangerous results following this treatment—of carbolic acid poisoning, embolism, sloughing and ulceration, or their sequelæ, abscesses or fistulæ—I have not witnessed any such results, and am loath to believe that they do occur if the operation be performed carefully and skillfully and with a proper observance of aseptic principles.

1610 ARCH STREET.

#### REPORT OF TWO CASES OF TUBERCULAR KIDNEY.\*

BY MILTON J. LIGHTY, M.D.,  
Alliance, Ohio.

CASE I.—Mr. F. C., aged sixty-eight, was admitted to the Allegheny General Hospital June, 1896, and placed under the treatment

\* Read before the Stark County Medical Institute, Ohio.

of Dr. Joseph C. Ohail, visiting physician to the hospital.

For many years he had enjoyed the best of health, though he was a hard laborer, exposed to all conditions of weather. During the last five years he had several attacks of rheumatism and bronchitis, and two years ago he first noticed a constant pain over the kidneys and in the abdomen about the umbilical and epigastric regions. At the same time micturitions became gradually more frequent and difficult. Six months ago he was obliged to quit work. The physical signs were those of a mild anemia, with an average hemoglobin of sixty per cent. and corpuscles 3,500,000. The lungs were apparently normal, heart slightly enlarged, vessels soft and compressible. Pressure over abdomen elicited great tenderness, and deep pressure revealed a slight nodule above the umbilicus. The urine was alkaline, containing phosphates and epithelial cells (no albumen, no casts, and no sugar).

Continued distress after meals, much pyrosis and several emeses, suggested an examination of gastric contents. After a test meal no hydrochloric acid was found, the absence of which indicated carcinoma of the stomach. The patient was chloroformed and a hard immovable tumor about the size of an egg, with smaller nodules surrounding it, was found to the right and above the umbilicus. Liver dulness and tumor dulness were inseparable. The position of the tumor was noted and after the patient had fully recovered from the anesthetic the stomach was expanded with gas, when it was found that the greater curvature of the stomach did not extend as low as the tumor, thus excluding involvement of the stomach.

The rectum and colon were then expanded with air, when it was found that a tympanic note followed the transverse colon separating hepatic and tumor dulness. From these observations it seemed apparent that the tumor was free from the stomach, liver and transverse colon, that it was retroperitoneal, and probably a cancer involving the glands of the mesentery. The lumbar pain was supposed to be a referred pain from the tumor, and the frequent micturition supposed to be caused by a cystitis from a retention of urine by a slightly enlarged prostate gland. A fatal prognosis was given and the patient put upon a purely palliative treatment.

Two months after admission it became necessary to use the catheter twice daily. Then pus and albumen suddenly became

abundant. The patient gradually grew weaker and died August 11, 1896.

At the autopsy the prostate was found enlarged, the abdominal tumor involved the mesentery and was composed of numerous nodules, many of which were suppurating. The kidneys were both enlarged to about three times the normal size and contained many dilated ducts and tubules filled with pus and plates of crystallized material. Miliary tubercles were found over the entire surface of the kidneys and over portions of the lungs. Microscopical sections show cheesy necrosis of the kidneys, and the tumor, instead of being a cancer, was a tubercular tumor also.

Though the case at first seemed like a cancer of the mesentery, it is fairly evident (from the late appearance of the pus and albumen in the urine) that the sudden supuration of the kidney was due to a secondary infection from the tubercular glands of the mesentery. The urine, unfortunately, had not at any time been examined for tubercle bacilli.

CASE II.—Mr. J. T. L., age thirty-six, laborer, came under my care December 1, 1896, with the history of scarlet fever at four years of age, a severe attack of measles at twenty, and repeated attacks of malaria until he sought a change of climate. During the last eight years he had had several attacks of influenza followed by chronic bronchitis. One year ago he first noticed pain in the back and on the right side, which has been constant since. There was a loss of appetite and weight attended with repeated irregular chills. Micturition was frequent and painful, followed by much tenesmus. The face was swollen; heart and lungs were apparently normal. An examination of the sputum was negative. The abdomen was rigid, with considerable pain over the stomach and liver, which was very much enlarged. Liver dulness extending three inches below the costal margin. Sounds were passed, revealing an absence of urethral stricture and stone in the bladder. The urine was 1018 in specific gravity, acid, with an abundance of pus and other sediments. Albumen was present in considerable amount even when the microscope showed an elimination of the pus after repeated filtrations. A diagnosis was made of chronic Bright's disease with an associated cystitis. The liver was supposed to be enlarged from amyloid condition of cancer; enlargement from a possible chronic malaria indicated by his frequent irregular chills was excluded by repeated ex-

aminations of the blood, which seemed free from the malarial plasmodium.

The treatment consisted of rest in bed, liquid diet, mild diuretics and tonics. With this regimen some of the symptoms improved for about one month, though the anemia increased. The pus and albumen diminished considerably and micturition was less frequent and painful. Repeated search was made for casts, with constantly negative results. I then made an examination for bacteria in the urine and found many tubercle bacilli, which, according to Strumpell, "are an infallible and absolutely decisive sign" of tuberculosis of the kidney. The patient rapidly declined and died in January, 1897, after seven weeks observation.

At the post mortem examination I found an enlarged amyloid liver. Numerous abscesses perforated the capsule of the right kidney, which was about three times the normal size, with many miliary tubercles. Microscopical sections showed a marked and advanced cheesy necrosis. This then was apparently a case of primary tuberculosis of the kidney in which perhaps fatal termination might have been delayed by an early operation, either nephrotomy or nephrectomy, which according to statistics from Ashhurst is successful in about 60 per cent. of cases.

Though the actual condition discovered so late in both these cases might not have been improved in either by any kind of treatment whatever, at the same time they clearly indicate to me the importance of an early examination of the urine for tubercle bacilli. Tubercular kidney covers perhaps from 3 to 5 per cent. of all the affections of the kidney, and is no doubt often mistaken for simple nephritis.

#### *SUCCESSFUL REMOVAL OF A CYSTIC ABDOMINAL TUMOR FROM A CHILD AGED SEVEN MONTHS.*

CAMPBELL, in the *British Medical Journal* for May 15, 1897, details the case of a child coming under his care with the following condition: The labor was difficult, forceps being applied high up. The child thrived well, and was apparently healthy at the age of three months, but about a month later the mother noticed swelling of the abdomen, which gradually increased. Periodical attacks of violent colicky pain occurred.

When it came under the reporter's observation the general nutrition was good. The respirations were shallow and embarrassed. The abdomen was greatly distended by a

lobulated tumor, which was more prominent on the left side, and felt hard in its upper half, but soft and fluctuating below. There was dulness on percussion all over the abdomen except in the right hypochondriac region, which was resonant.

On July 10, two days after first examination, it was chloroformed and a median incision made from midway between the ensiform process and navel to midway between the navel and symphysis pubis. This exposed a large tumor lying behind the posterior parietal peritoneum and pushing the intestines into the right hypochondrium. The cystic portion having been tapped, the whole mass was enucleated from the subperitoneal tissue. No bleeding of consequence occurred, and no ligatures were required. The tumor had no pedicle, but was firmly attached deep in the left side of the pelvis. It lay in front of the left kidney, which was situated at the level of the iliac crest, and was freely movable. The peritoneal covering of the tumor was attached to the edges of the lower end of the abdominal wound, and the cavity was packed with gauze. The upper end of the wound was closed by two layers of sutures, silk being used for the peritoneum and silkworm gut for the skin and aponeurosis. The operation was well borne, except for a few seconds during the extraction of the tumor, when the pulse became bad, apparently owing to pressure on the cardiac area of the diaphragm.

Two hours after operation the child took milk and barley-water, and afterwards fed regularly every two hours. Fifteen minim doses of whiskey were given every half hour for the first three hours. The child slept well. She vomited slightly on one occasion only. On the sixth day the gauze packing was removed, and the bowels acted spontaneously. On the eleventh day the silkworm-gut stitches were removed. Recovery without interruption.

The tumor was composed of a cyst containing about ten ounces of clear yellow fluid, and of a solid portion, in which a mass of cartilage and a piece of bone lay embedded. It weighed three pounds when fresh. There was nothing to indicate the organ from which it originated.

This appears to be the youngest child from which a cystic abdominal tumor has ever been successfully removed. The only case which approached it in point of youth is that operated on by Roehmer, of Berlin, in 1883, at the age of twenty months. The present case is therefore thirteen months younger than the Berlin one.

### NON-MEDICINAL METHODS IN THE TREATMENT OF DISEASES OF THE HEART.

The so-called Schott method of treatment of heart disease consists in large part of passive movements of the limbs of the patient and in certain cases a resort to moderate and graded exercises. As carried out at Nauheim it possesses the additional advantages that the patient gives himself up entirely to his cure, and nothing is left undone which can aid the special movements and the baths in improving the nutrition of the tissues and the condition of the peripheral circulation. At first sight this recently advocated, but by no means entirely new, method which Schott has urged has been cited as an example of the fact that the treatment of heart disease by rest is not so important as some of the profession have been led to believe, and it has been thought by some that rest as compared to this newer treatment by exercise is by no means so valuable a remedial measure as we have thought.

We believe, on the other hand, that the so-called Schott treatment of cardiac disease is necessarily limited to a very much smaller class of patients than is the treatment by rest, and we see nothing contradictory in the application of these two non-medicinal measures for the treatment of cardiac lesions.

On the contrary, we think that the results which have been obtained by advocates of the method forcibly illustrate the fact, so well recognized by all therapists, that all cases cannot be benefited by the same treatment and that what benefits one may actually do harm to another. Nor is there any contradiction in these two methods, for the Swedish movements do not in any way necessarily impair the rest which the heart of the patient may receive by means of his personal inactivity. On the contrary the work of the heart, even with the resistance movements which are practiced in the methods of Schott, is not very materially increased, while on the other hand a large amount of labor is taken away from the heart by the fact that the muscular contractions so improve the circulation in the various lymph spaces of the body that the heart is considerably aided, and instead of its being the only organ employed in causing a circulation of fluids in the tissues of the muscles of the body, there are other aids in propelling blood and in forcing it along in the lymph paths. As a result of this the peripheral portions of the body are not continually irritating the heart by calls for more blood, neither do they become congested with stagnant and over-used fluid. The general nutrition of the entire body is improved, and simultaneously with this improvement comes a change in the nutrition of the heart.

The moral seems to be that while nearly all cases of cardiac disease with ruptured compensation require rest, many cases in order that their general health may be improved require at the same time a certain amount of muscular movement. A practical application of this idea is already familiar to the profession in carrying out the rest-cure, in which, as is well known, the patient is placed in bed, prevented from making any exertion, but his or her circulation and nutritive processes are maintained by massage in the morning and electrical stimulation in the afternoon, not to speak of the bath and the cutaneous rubbing with a towel which is resorted to while the patient lies prone on a blanket, every morning. Unless these measures are carried out in addition to the rest it

is evident that all the benefits from the so-called rest treatment of cardiac disease cannot be obtained. In a recent number of the *Medical Record* Dr. Beverley Robinson of New York discusses not only the rest-treatment of cardiac disease and that which has been recommended by Schott, but he also dwells upon the advantages and disadvantages of the method instituted by Oertel, a method which had the design of improving the general circulation by more or less active muscular exercise taken by the patient, as a rule in the form of mountain-climbing. We understand that in Europe at least Oertel's method has greatly decreased in popularity because its technique was excessively rigorous, and the reason that the resistance movements of Schott seem to do more good, and to be more popular, seems to lie largely in the fact that they accomplish the same result without producing any degree of exhaustion of the heart or general nervous and muscular systems.

*THE USE OF ANTISTREPTOCOCCIC SERUM  
IN THE TREATMENT OF  
VARIOUS FORMS OF  
SEPTICEMIA.*

---

The very interesting studies which have been made during the last few years in regard to immunity, and our ability to produce it in animals and in human beings, has resulted, first and foremost, in the employment of diphtheria antitoxin for the protection of persons who are infected by the Klebs-Loeffler bacillus, and the extraordinary results which have been obtained by the use of this serum in the treatment of this disease have placed its use upon as firm a basis as that upon which any therapeutic measure can rest.

Naturally experimenters and clinicians have gone further than this and have attempted to use other serums prepared in ways identical with or only slightly different from the methods employed in the preparation of diphtheria antitoxin, for the protection of individuals suffering from an infection with other malignant germs than those of diphtheria. One of the most noteworthy attempts of this character has been the employment of the so-called antistreptococcic serum, or the serum obtained from animals supposed to be rendered immune to the streptococcus, in persons who are suffering from septicemia following injuries, surgical operations, or parturition. While the scientific information upon which this treatment is based amply justifies the employment of antistreptococcic serum and

other serums destined for similar purposes, it is an unfortunate fact that the results which have been obtained by its employment so far have not been such as to give us the encouragement which the early studies with regard to diphtheria antitoxin gave us. Medical literature, particularly in England and in Europe, has teemed during the last few months with isolated reports of cases of septicemia treated by this means, and some clinicians have even gone further and employed this serum in the treatment of such a disease as scarlet fever, in which, in addition to a specific infection, it seems probable that grave streptococcic infection also occurs. It is worthy of note, too, that in the treatment of scarlet fever results have been obtained which would certainly justify the experimenters in continuing the trial of this substance, although they have hardly been sufficiently numerous or so universally successful as to justify the average American physician in following in their pathway. Perhaps the most notable contribution which has been made in American medical literature to the study of this question is a series of papers recently communicated to the Section on Gynecology of the College of Physicians of Philadelphia by Hirst, Norris, Shoemaker, Davis, Baldy and Shober. These papers combined are so exhaustive that it is not possible for us to give more than a summary of the views of their individual authors. Dr. Hirst from his experience in the employment of antistreptococcic serum in puerperal sepsis believes we are not in a position to pronounce any judgment on this new treatment; that we should not be so prejudiced against it as not to give it a thorough clinical test, and on the other hand should not be too enthusiastic concerning it. As he well points out, the following forcible objections can be urged against this method of treatment: First, the well tried, older plans of treatment will result in the cure of about four-fifths of the cases. If, therefore, the serum is employed along with other suitable treatment, four out of five cases will be cured in all probability, and some of these cures may be erroneously attributed to the serum. Next, he points out the difficulty of obtaining a thoroughly reliable preparation, which difficulty has been largely obviated within the last few weeks by the placing upon the market of a reliable preparation. Third, he believes that the use of this remedy must be always more or less empirical, for while it is true that most cases of puerperal infection

are due to streptococci, there are others which suffer from a mixed infection or in which the streptococcus is not present at all. Again, the treatment is not entirely free from risk, for several French observers have reported deaths in which the result was apparently unmistakably due to the serum. Again, its use may cause the physician to be careless in the employment of other necessary remedial measures. And, finally, we know nothing as to the real method by which the serum does good. Norris concludes the report of a case in which he employed the serum by stating that very strong clinical evidence of streptococcic infection should be had before resorting to the employment of antistreptococcic serum in the treatment of puerperal sepsis.

Shoemaker's case, one of septicemia occurring after abortion, was treated in this manner, but the patient nevertheless died. Davis expressed the belief that this method of treatment must be employed early, in connection with stimulating agents, and we may then hope for a good result in a small number of cases if they are seen promptly; while Baldy seemed to think that the death of his patient resulted from the administration of the serum. He states that while it is possible that death occurred by coincidence after the administration of this treatment, he will nevertheless in future use the serum, if at all, with the utmost caution and distrust.

The contribution to this symposium made by Shober consisted in a series of twenty-one cases collected from the *Lancet* and *British Medical Journal* during 1896. Shober concludes that to obtain the best results it is of prime importance to obtain reliable serum, that the case should be one of unmixed infection, that the injections ought to be commenced upon the onset of symptoms, and, finally, that it is highly important to employ intra-uterine and vaginal treatment in connection with the serum treatment.

---

#### POISONING BY QUININE.

---

In a number of issues of the THERAPEUTIC GAZETTE we have called attention in its editorial columns to the fact that quinine is one of those drugs which very frequently produce untoward symptoms in patients who are unduly susceptible to it, and the development of curious circulatory and skin symptoms which can not be referred to any ordinary cause will often be found to be due to quinine

which the patient had prescribed for himself or herself. The number of cases in which quinine has produced symptoms varying in severity from gastric disorder with headache and deafness, to delirium, coma, blindness, and absolute deafness are a multitude. Sometimes delirium and marked vertiginous symptoms have been produced.

On the other hand, instances in which the drug has been taken in doses large enough to produce death are certainly exceedingly rare. Stillé tells us that Malier has recorded four such cases. In the first the patient suffered from delirium and coma and died on the second day; in another by Guersant, a man and his wife between them took nearly five ounces of the sulphate of quinine within the space of eight or nine days, the husband dying but the wife recovering. The smallest dose of quinine which has produced death is probably that recorded by Baldwin in *The American Journal of the Medical Sciences* for April, 1847, in which a child of six years died from taking eight grains of quinine in two doses, after an interval of three hours preceding the second dose. In all these cases it is interesting to note that the symptoms found at the post mortem examination were identical with those found in animals which died from large doses of quinine. On the other hand enormous doses of quinine have been taken without fatal consequences. Thus Guersant has recorded the case of a lady who took 600 grains within the space of a few hours, and Dietl gave a woman with epilepsy no less than 120 grains a day, this dose being arrived at by gradually increasing doses. Another case is recorded of an old woman who used 10 grains of quinine every two hours until 100 grains had been taken, without any bad effects having been produced. Our attention has been called to this matter by the report of a case by George Gresswell in the London *Lancet* for May 1, 1897. The patient was a woman of forty-seven years, just past the climacteric, who had, fortunately for herself, vomited about a quart of what she had taken for her breakfast after taking the poison. The history revealed the fact that the patient had taken two teaspoonfuls of quinine at the very least and shortly afterward seemed to be in a fit. Her hands and face were extremely pale, the pulse was quick and irregular, fluttering, small, thready, and feeble. The pulse was 120 a minute. Six or seven hours after the poison had been taken the patient was still speechless and quiescent, but not wholly unconscious. Long after consciousness had

returned and the patient's condition had improved her deafness was very marked, the pupils were contracted and reacted to light very slowly. Three days after the quinine had been taken an examination of the patient showed her pulse to be 72, her heart's action still feeble, and the presence of a slight pre-systolic mitral murmur. The deafness entirely left her.

Cases in which such large doses of a common drug such as quinine are taken with distinctly deleterious results are of very considerable interest, and for this reason we have thought it wise to call attention to the case recorded by Gresswell.

#### INTRAPERITONEAL DRAINAGE.

The question of intraperitoneal drainage is exhaustively considered from a clinical standpoint by Dr. John G. Clark, in the *American Journal of Obstetrics* for May, 1897, his conclusions being founded upon a critical review of seventeen hundred cases of abdominal section. Considering in the first place the subject of drainage in cases not primarily infected, it has been shown that if there has been excessive traumatism, blood and serum may accumulate in the dependent pockets and become encapsulated. This blood, however, does not lose its vitality immediately, but remains actively germicidal. Of one hundred ovarian cases but one was complicated by the formation of ovarian abscess after operation. In one hundred similar cases which were drained eight such sequelæ occurred. This tends to show that coagula rarely suppurate even though left to the care of a disabled peritoneum.

Experimental studies show that when an infected material which is difficult or impossible of absorption is introduced into the peritoneal cavity, peritonitis invariably occurs. The toxic effects are virulent and rapid in proportion to the injury to the peritoneum. It is consequently clear that the introduction of a foreign body into a peritoneal pocket would make a dangerous communication with the skin of the abdominal wall.

The streptococcus pyogenes is the most virulent organism, next comes the staphylococcus aureus, while the staphylococcus albus is the least harmful. The strict localization of the great majority of stitch abscesses, however, proves that the growth of the aureus—the common organism—is easily inhibited. Infection with the strep-

tococcus, however, is commonly followed by marked septic symptoms, often terminating in death. The staphylococcus albus excites very slight reaction, although exceptionally it may produce a fatal peritonitis. The colon bacillus is also mildly toxic. It is nearly always found in perineal operations, though these cases run almost without exception a favorable course. The air organisms usually found in the projecting end of the drain for a short distance below the surface give rise to no reaction.

The danger of infection from the drainage tract is greater after the first removal of the drain than immediately after operation. In a few hours a cement-like fibrinous envelope is formed about the drain, binding the adjacent peritoneum and gauze together in the closest apposition. Attempt to remove the drain is extremely painful and may tear adhesions. In one instance fatal hemorrhage resulted from dislodgment of ligatures. During the process of organization, usually about the fifth day, the layer of fibrin in contact with the gauze degenerates, and the close band of union between the gauze and the peritoneum is dissolved. Large drain cavities are likely to refill with serous and hemorrhagic fluid after the removal of the drain; the abdominal opening may then become closed, thus preventing the escape of the infected fluid, when if it is not liberated by incision or dilatation of the drainage tract it may rupture into the general peritoneal cavity.

Clark considers the establishment of communication between intraperitoneal devitalized clots of blood and the exterior extremely hazardous. He holds it is much safer to allow small encapsulated collections of blood, like those found after the early rupture of ectopic pregnancy, to be disposed of by the means at Nature's command. Where these collections show signs of infection, or where there is danger of secondary rupture from further growth, if they cannot be removed from above Kelly's plan of puncturing and evacuating through the vagina should be followed. After operation the infection of the sac is prevented by the disinfectant properties of the normal vaginal secretion. In a recently ruptured case the conditions are different. There are free clots in the peritoneal cavity which if infected will cause death. Under such circumstances an abdominal operation is the only available course to pursue.

Considering drainage where infectious matter was supposed to be present during the

time of operation, it was shown that the pelvic accumulations of pus rarely contain active organisms at the time of operation. Of forty-four specimens staphylococcus albus and aureus were found once in culture. Fifty-six uteri were examined; in none of these were organisms found in culture. Schauta records 144 cases, with streptococci and staphylococci found in four, hence it is clear that infection of the peritoneum from the diseased area at the time of operation is not likely to occur, as the initial infecting organisms have disappeared.

With a view of ascertaining the merits of drainage Clark has selected two series, each of one hundred cases, of pelvic inflammatory disease, in one of which all were drained and in the other none were drained. These series were as nearly alike as possible. Untoward results are recorded, including fatal and complicated cases, in twenty per cent. of the undrained cases, 54.5 per cent. of the drained. There were persistent vomiting, vesical irritation, abnormal rise of temperature, and tympanites in fourteen per cent. of undrained cases and forty-one per cent. of drained; there was suppuration of abdominal wound in eleven per cent. of the undrained cases and twenty-four per cent. of the drained. Post-operative inflammatory deposits are recorded in one per cent. of the undrained cases and eight per cent. of the drained. There was a mortality of six per cent. in the undrained cases and thirteen per cent. in the drained. The tables demonstrate that the danger of rupture in intraperitoneal pus sacs is greatly overrated. There is nevertheless the possibility that virulent organisms may be present. Hence great care should be exercised in preventing the accident.

The higher mortality of the drained cases is largely due to infection through the medium of the drain. Fecal fistulæ followed drainage once in 1700 cases. It was due to pressure necrosis produced by the glass tube. At the end of the third week, the day after the removal of the drain, fecal matter began to escape from the drainage tract. In three other cases gas and small particles of fecal matter escaped from the drainage tract, but in each instance the opening closed before the patient left the hospital.

Russell finds that in at least eight per cent. of cases in which extensive drainage has been used hernia has followed. Buried wire sutures employed to close the abdominal wound have, however, decreased the danger of this complication. When drainage is employed a row

of mattress sutures are buried along the line of incision down to the drainage sac.

Even when suppuration occurs granulations commonly form about the wire and healing takes place rapidly, although sometimes it is necessary to remove the sutures because of persistence of the discharge.

To avoid the sepsis ensuing after drainage the hands should be thoroughly disinfected. Zweifel's rule, that at least three days should supervene after contact with infectious matter before performing an abdominal operation, is a good one. Hemorrhage should be stopped by ligature, twisting and clamping. When oozing persists the peritoneum should be allowed to take care of it. Care must be taken to avoid bruising or injuring tissues. The general peritoneal cavity should be isolated during operation by walling off with gauze pads and non-absorbing cotton bolsters enveloped in gauze. As little of the peritoneum should be sacrificed as possible; bodily heat should be conserved, since it has been shown that resistance to infection is greatly decreased by lowering the temperature of the intestines; care should be taken lest intraperitoneal abscess rupture; the peritoneal cavity should be thoroughly irrigated with normal salt solution after operations during which débris or fluids have escaped into it. When the operation has been prolonged from one to two pints of normal saline solution should be introduced into the peritoneal cavity and the foot of the bed should be elevated eighteen inches for the first twenty-four hours.

If symptoms of infection arise after operation salt solution should be injected into the cellular tissues beneath the breasts. By elevating the pelvis after operation the normal peritoneal current may be assisted greatly by at once draining out the dead spaces. The infectious organisms are quickly carried into the lymph channels and are destroyed before they can increase in numbers, and toxic substances elaborated with the organisms are diluted and prevented from extending their irritant effects upon the wounded area. This posture, however, is not a curative measure after general peritonitis has developed. Free drainage is indicated under such circumstances, as the lymph channels are choked.

Drainage may be indicated in appendicitis when the stump cannot be securely closed or when the appendix is ruptured and has caused an abscess. If operation is performed in the early stage drainage should be omitted. Localized collections of pus in the pelvis should be drained through the vagina, unless

they can be cleanly enucleated. In excision of fistulous tracts leading from the intestine to the abdominal wall drainage may be indicated, since the suture frequently does not hold. In purulent peritonitis drainage is usually advised. Pawlowsky has shown that the lymph channels are choked with the infectious bacteria and inflammatory products; hence, thorough irrigation and free drainage through an abdominal incision are indicated.

As to the method of drainage, one or more strips of plain sterile gauze, doubled backward and forward like the folds of a fan, should be packed in; it should be lightly withdrawn and cut off as soon as the external end becomes dry. By the fifth day it should be entirely removed. When a second set is packed great care should be observed not to break up adhesions. The pelvis is most safely drained through the vagina. These drains are left in place five days and are replaced by a fresh strip of gauze, if it is necessary to keep the cavity open. To do this the patient should be placed in the lithotomy position across the bed and the vaginal opening exposed with a Sims speculum.

This contribution of Clark's, voicing, as it doubtless does, the opinions of Dr. Howard Kelly, is the most valuable and convincing paper which has appeared upon the subject. His conclusions are founded on years of faithful laboratory and bedside study, and are proven by the tabulations and statistics which are given.

---

## Reports on Therapeutic Progress

---

### *THE TREATMENT OF TYPHOID FEVER IN CHILDREN.*

F. GORDON MORRILL, of Boston, contributes an article on this comparatively rare affection of childhood to the *Archives of Pediatrics* for March, 1897. He believes that there can be no doubt of the necessity of adequate feeding, whether the case is that of an adult or child; and experience has therefore proved that milk is the safest and most convenient form of nourishment as well as the most grateful to the child, whose anorexia is complete, but whose thirst is fortunately great, during the acute stage of the fever. It should be given every two or three hours in four-ounce portions (less to very young children), and it is seldom necessary to dilute it, unless during temporary attacks of nausea or vomiting (common enough in typhoid), when the addition of lime-water or Vichy and the ad-

ministration in small but frequently repeated doses are indicated.

Sleep is often disturbed, and advantage should be taken of the fact to give milk during the night as well as the day. In this way a child five years old will take from eighteen to thirty ounces in twenty-four hours, and older ones in proportion, up to fifty ounces, which seems to be about the average limit of their capacity. Should nausea and vomiting be persistent, in spite of the measures described above, withdrawing the milk entirely and substituting egg-albumen water in teaspoonful doses (to which a few drops of brandy may be added) seldom fails to promptly relieve a trouble which, as a rule, lasts a day or two only at the most.

In cases where there is any marked degree of prostration stimulants are of the greatest value, and their immediate effect on the pulse and general condition of the child is pleasant to witness. Brandy in drachm doses *ter in die* is often sufficient for a child, although the writer has known eight times this amount to be given in twenty-four hours. He believes that a majority of all children with typhoid fever are distinctly benefited by the judicious use of alcohol; and of forty odd cases which entered his wards during the past autumn seventy per cent. were given brandy in amounts varying from one drachm three times a day to two drachms every two hours, at some period of the attack. The largest quantity was given during the acute stage of a second relapse, and the patient recovered.

Cold water is often craved and may be given pretty freely in cases where an ordinary quantity of milk fails to quench the thirst; but if there is the slightest difficulty in adequately nourishing the child, thirst must not be wasted in this way—the milk is to be insisted on.

During the acute stage of the fever there is less danger of digestive trouble if a milk diet is rigidly adhered to; but as soon as the temperature becomes normal, or assumes a low range, or sharp morning remissions, together with the patient's improved aspect, which signal the speedy attainment of convalescence, some predigested form of starchy food and somatose (which he has used with beneficial results in a number of cases) should be added to the diet. The liability to reinfection must be borne in mind (seventeen per cent. of one hundred recovered cases at the Children's Hospital have had relapses), and whether the patient's improve-

ment is followed by recovery, or merely precedes a few days which intervene between it and a relapse, an increase of nourishment in proper form will hasten the advent of health, or get the child in better condition to stand a fresh siege. When convalescence (slow and tedious in the mildest cases) is fairly established, a diet appropriate to the age of the child may be safely prescribed, and its ravenous appetite nearly if not quite satisfied.

The author has never seen the Brand method employed, and has had no experience in any special form of medication in the enteric fever of childhood, which tends to recovery, and runs a very close second to frank pneumonia, as a paradox, when its results are compared with those of the same disease in adults.

In the early stage, if there is constipation, calomel, both as a purge and intestinal disinfectant, may be given. It can cause no mischief (even in the massive European dose), and may be safely used. One-tenth of a grain every hour is usually enough to produce a result in eight or ten hours. Should the bowels remain inactive after a first thorough evacuation, glycerin enemata may be given every other day. If diarrhea is present in the early stage, calomel may still be given before employing other remedies to check the trouble, which so far as he has observed yields more readily to salicylate of bismuth in five- or ten-grain doses than to any other drug which does not contain opium.

To reduce a high temperature which is poorly borne, cool bathing may be employed; but the results are very temporary, and the average drop in the temperature ( $1.5^{\circ}$  F.) hardly compensates for the extra work involved. Occasional doses of lactophenin are very effective and do no harm, so far as his experience goes, in any case where there are not obvious contraindications to its use. Lactophenin will produce an average drop of  $3.5^{\circ}$  F. in four hours. These figures are taken from careful records of the temperature in sixty-five instances in which the drugs were used. Restful sleep may often be obtained in this way. Children vary widely in their ability to bear hyperpyrexia, and on several occasions he has observed one with a rectal temperature of  $105^{\circ}$  F. sitting up in bed and amusing itself with books or toys.

When the first sound of the heart is soft, and alcohol fails to regulate a weak or irregular pulse, digitalis is most useful. When dis-

turbed sleep is not due to a high temperature, a five-grain dose of trional acts admirably as a hypnotic. Aside from the remedies above mentioned he has found little use for drugs in average cases.

The most frequent serious complication which one is called upon to treat is that which results from the intestinal lesions failing to heal as is customary. Hemorrhage in a child varies from very slight loss of blood with each discharge, which may continue for days, to copious and fatal bleeding of which the thermometer may give no warning whatever. In case of any considerable hemorrhage, the foot of the bed must be raised, ice-bags applied to the abdomen, and gallic acid, opium, and lead given by the mouth, or ergotin by hypodermic injection. Injections of a normal salt solution into the cellular tissue may also be tried where marked prostration and anemia are observed. Perforation, if in a position to cause general peritonitis, is fatal, and nothing more than a free exhibition of opium is indicated, unless some bold surgeon can be induced to do a laparotomy. Bed-sores are rare and easily prevented. They would be far more common, as would hypostatic congestion of the lungs, if children did not frequently change position of their own accord.

Acute delirium is rare, but forcible restraint, or a "reminder" in the form of securing one or both hands to the frame of the bed, is occasionally required. Ominous nervous symptoms (strabismus, somnolence, retraction of the head, intense cephalalgia) appear in rare instances, and often vanish so promptly as to preclude the possibility of their having been due to organic changes. Mental disturbances almost invariably tend to entirely disappear, and call for no special advice or treatment. Retention of urine is rare, but daily percussion of the suprapubic region should never be omitted in cases where there is any suspicion of a lack of intelligence or care on the part of the attendants.

Diapers and bed-linen must be carefully looked after. They should be soaked in a 1-to-40 solution of carbolic acid for six hours, then boiled, and washed in vessels kept especially for this purpose. Discharges which are received in bedpans are to be covered with a 1-to-20 solution of carbolic acid, and after being thoroughly broken up are to stand twenty minutes before being emptied. The hopper and bowl of the closet should be washed in 1-to-20 solution daily. The nates should be carefully wiped with a 1-to-40 solu-

tion after each discharge, and the cloths with which this is done treated in the same way as the diapers. Rubber covers should be placed under the sheet on which the patient lies, and carefully washed off with a 1-to-20 solution if they become soiled. Thermometers should be carefully disinfected as well as washed each time the temperature is taken. The attendants should refrain from eating or drinking while in the immediate vicinity of the patient, and should wash their hands and use a nail-brush several times a day. The remains of food or drink which are brought from the sick-room should be thrown away, and all eating utensils washed in a 1-to-40 solution of carbolic, then immersed in boiling water, before they are allowed to return to ordinary use. All articles of clothing which come in contact with the patient must be disinfected and washed apart from those of other members of the household. Mattresses should be aired in the sun for several hours daily for a week after the patient recovers. When one reflects upon the infinite variety of ways in which typhoid bacilli may be carried (furniture, food, drink, utensils of all sorts, and in the air itself under certain conditions), it is a matter of surprise that the disease is not more prevalent—as it doubtless would be if the micro-organism (like that of diphtheria) did not require a special soil in which to flourish and prove its virulence.

#### THE TREATMENT OF FURUNCULOSIS.

In the *Journal des Praticiens* of January 23, 1897, ROBIN recommends the following treatment for boils:

The skin is first washed with water and pure soap, and afterwards the following prescription made up into three cachets is administered:

- ℞ Sublimed sulphur, 2½ drachms;  
Powdered camphor, 30 grains.

As soon as a point of redness appears in the skin a small compress is applied over it, which will often abort the boil. If the boil has already actually formed the complete evacuation of its contents is needed, and after it is opened the following should be applied to it:

- ℞ Sublimed sulphur, 2½ drachms;  
Powdered camphor, 2½ drachms;  
Glycerin, enough to make a paste.

After this has been applied for twenty-four hours the part should be washed with boric-acid water and atomized with a 1-to-100 solution of carbolic acid, and then the application of the sulphur paste should be repeated.

#### PURULENT OPTHALMIA OF THE NEW-BORN.

The New York *Medical Record* contains an editorial on this important and ever interesting subject in its issue of March 13, 1897. In its course it points out the well recognized fact that of the many dangers attending the newly-born infant ophthalmia neonatorum is the most to be dreaded. It is stated that one-third of all the blind in Europe become so from this cause. Its early recognition and unremitting treatment are of the utmost importance. In every obstetric case the physician should gently separate the lids of the infant, to assure himself definitely of the presence or absence of any eye discharge. Infection from the maternal passages manifests itself almost invariably by discharge on the third day, both eyes being affected as a rule. Discharges appearing at a later period usually arise from soiled hands, towels, or sponges; and only one eye may be primarily attacked. This conjunctivitis is never due to strong light or cold, as is popularly supposed, but has a definite specific origin.

Following a discussion of the Medical Society of Breslau concerning Crêdé's method of treating such cases with the aqueous solution of nitrate of silver (one grain to a drachm of distilled water), twelve thousand question blanks were sent out to physicians, with results that form an important contribution to the subject. These blanks were distributed throughout Germany, Austria, Switzerland, Belgium, and Holland. Reports were returned giving statistics of eye disease in 302,971 new-born infants. Of these, 1938 suffered from ophthalmia neonatorum. In Germany, sixty per cent. of eye disease was of this nature; in Austria, eighty per cent.; and in Switzerland, Belgium, and Holland together, ninety per cent. In all these cases the characteristic condition appeared within five days in seventy-six per cent. of the infants under observation. The discharge began after the fifth day in twenty-four per cent. In one-fourth of the entire number of cases one eye was attacked primarily; in three-fourths both were affected simultaneously. Seventy-one per cent. were completely cured. Nine per cent. discontinued treatment. Twenty per cent., or one-fifth of the 1938 cases, retained permanent lesions of more or less severity.

This twenty per cent. presented corneal scars, monocular or binocular; and one-half of these permanently damaged infants became totally blind. It was considered they were

brought too late for cure—fifty per cent. of the blind babies were not seen until the ninth day of their disease, and twenty-five per cent. not until the fourteenth day.

Out of one hundred representative ophthalmologists consulted, seventy-nine were in favor of making Cr  d  's method obligatory in routine obstetric practise. It is not difficult, does no harm, and may avert dreadful catastrophe. The eyes are first carefully washed with tepid water, and the lids thoroughly cleansed by means of absorbent cotton. A few drops of the two-per-cent. solution of nitrate of silver are then instilled into each eye. Materials used to wipe away the discharge must be burnt or otherwise destroyed. Twice daily some simple ointment should be applied to the margin of the lids, to prevent them from sticking together. In severe forms, when there is much swelling and a thick discharge gushing from between the lids, the foregoing nitrate of silver solution may be used every six hours. When the inflammatory action subsides, Muskett recommends that weak solutions of alum, sulphate of zinc, and perchloride of mercury be substituted. The astringent lotion may consist of from four to ten grains of alum or from one to two grains of sulphate of zinc to the ounce of water. Either of these may be used with freedom and safety. The mercury solution gives excellent results—one-half grain of the perchloride to six ounces of distilled water. Cold-water compresses give great relief after active treatment.

Should ulceration of the cornea ensue in spite of active and earnest measures, the eserine treatment introduced by De Wecker may prevent perforation in even the worst cases. Four grains of eserine in one ounce of distilled water is the strength usually employed, though sometimes one grain to the ounce is better borne. A few drops are instilled into the eyes six times a day. This treatment is also of value in a form of corneal affection peculiar to infantile purulent ophthalmia, mentioned by Nettleship, in which the cornea becomes rapidly and almost entirely opaque. Marginal ulcers are not so serious as those centrally situated, and sight may be preserved. More than in any other disease, Dr. J. Lewis Smith urges the necessity of employing faithful and attentive nurses, who will carry out punctually the directions given. Two nurses are required, one for day and the other for night duty, since it is essential that the eye be frequently cleansed and the secretion washed away.

#### THE USE OF ANTITOXIN IN THE TREATMENT OF DIPHTHERIA.

It should be the duty of every practitioner to place the antitoxin at the head of all therapeutic measures that he may know of for the cure of diphtheria, for it proves its efficacy whenever it is administered early, and in sufficient quantities to neutralize the poison which it is to antagonize. This is the opinion of Dr. DUFFIELD, of Detroit, as expressed in an article in the *Journal of the American Medical Association* of March 6, 1897.

An early diagnosis cannot always be made from the clinical symptoms; frequently a tonsil may be covered with spots like a follicular tonsillitis, and one of the spots be true diphtheria and the case treated for an ordinary tonsillitis, when in reality a true case of diphtheria is developing in a medium that will prove a regular hotbed for the development of the Klebs-Loeffler bacilli.

All cases suffering from sore throat should receive the benefit of the doubt as to whether the case be one of simple or diphtheritic sore throat by a bacteriologic examination, and the earlier such an examination is made, the greater the chance of saving our patient.

The Detroit Board of Health has furnished test-tubes for the making of cultures from suspected sore throats, and the writer believes that if they were used more often the epidemics in Detroit would be reduced.

The dose to be administered at first is a question of importance. He thinks it is better to overdose at first than to give a lesser curative serum. The bulk is the same, whether 500, 1000, 1500, or 2000 units are used, and as the inserting of the needle is always painful it is better to give a full dose early, rather than to have to repeat the injection.

The amount to be used depends upon the length of time the patient has been sick, the extent over which the membrane has spread, and the thickness of the membrane.

As to the antitoxin to use, having tried five or six different makes in the past two years, he has found that which is manufactured by Parke, Davis & Co. most efficacious. Apart from the potency of this brand, he states that he must commend the ingenious manner in which it is marketed, viz., in hermetically sealed glass bulbs, which exclude the air and keep the serum strictly aseptic.

From the charts he exhibited it could be seen that when a dose was given of sufficient strength the action on the toxin producing the constitutional symptoms—namely, fever,

high pulse, and great prostration—was prompt and effective; the fever being reduced rapidly. Laryngeal cases recovered slowly, but showed marked improvement after each injection.

Strange as it may seem, the serum varies in strength, different manufacturers furnishing the same number of units in various bulks, and many brands containing a less number of curative units than claimed. Such brands are to be avoided. The most concentrated serum is, he thinks, the best to use, as there are rarely any bad results from its injection. It has been noted in several cases that an erythema or urticaria develops around the point of injection. None of the severe symptoms as noted by some have been noticed by the writer, though several hundred injections have been given under his direction. Several have had rheumatic pains, but no other symptoms showed themselves, not even an abscess, and their absence was probably due to the great care used in the manufacture of the serum administered.

During the past year there have been 111 cases of diphtheria in Harper Hospital, five of which died. Three of these entered moribund, and one man had been sick six days before entering the hospital, and the action of the toxins upon his heart centers was so great that he died from heart failure, the result of the diphtheritic poison. Some cases where large doses of antitoxin were used close together showed subnormal temperature for several days. There have been six tracheotomies and twelve intubations. There have been many laryngeal cases that were treated successfully merely with antitoxin and inhalations. The youngest case was a child of five weeks, bottle-fed. During the months of October, November, and December there were over seventy cases in the hospital under the author's care, and six in private practise.

The nurses who were on duty were at first immunized with 250 units, later with 500 units, and still later with 1000 units, as the prophylactic effect was better. The nurses were constantly, except when off duty, exposed in an atmosphere saturated with diphtheria. Two nurses took the disease after having been immunized, and one took diphtheria after nursing a man who started with "follicular tonsillitis," but which later turned to a true diphtheria. All the nurses recovered. When the disease was taken by those who had been immunized the attacks were mild.

In all the hospital cases the patients had been sick from two to three days before entering, hence it was necessary to use the strongest antitoxin serum early and repeat the dose in six, twelve, or twenty-four hours, if the growth of the membrane was not checked or stenosis promptly relieved.

The resident physicians have several standing orders that patients receive as soon as they reach the hospital, for they believe in using some medicines that proved useful before the discovery of the antitoxin.

An examination of the throat is made to see the extent and location of the membrane, and the following treatment is instituted:

1. A hypodermic of antitoxin, 1500 or 1000 units.
2. A liberal dose of calomel if tongue is coated and bowels constipated.
3. An ice-collar, worn until all glandular enlargement disappears.
4. A gargle every two hours of hydrogen peroxide two parts, euthymol two parts, lime-water four parts.
5. Membrane to be touched for ten or fifteen seconds with Loeffler solution every three hours. This is composed of:

Menthol, 10 Gm.;  
Toluene, q. s. ad 26 Cc.  
Creolin, 4 Cc.;  
Iron chloride solution, 4 Cc.;  
Alcohol, q. s. ad 100 Cc.

This dissolves the membrane and destroys the Loeffler bacilli *in situ*.

Should the patient be needing a stimulant, the calomel is omitted and whiskey or strychnine administered. Other symptoms are met by appropriate means as soon as they arise.

Cases of laryngeal diphtheria are treated with steam inhalations after being injected. Children with pneumonia complicating diphtheria are put in the oil-silk jackets and kept in an atmosphere of compound tincture of benzoin and other non-irritant inhalations.

The frequency of dose of the antitoxin depends upon the spreading of the membrane and the condition of the temperature.

How soon is a patient to be discharged as cured? The writer has a culture taken from throats each day for three or four days until all Klebs-Loeffler bacilli disappear before he pronounces the cases well enough to mingle with others, for it has been known that the Klebs-Loeffler bacilli may be carried in the throat of a person without danger to himself, and yet be a source of great danger to others.

As a rule the cultures taken after all membrane has disappeared from diphtheritic

throats prove negative after three or four days.

Just how dangerous the diphtheritic bacilli are after the use of the antitoxin remains for the bacteriologist to determine. Where antitoxin has not been used he has known reinfection to occur ten or fourteen days after the primary attack.

Diphtheritic paralysis developed only slightly in two cases, but more severely in another case where all the vital centers had suffered from previous disease. Albuminuria was noted in a few cases, but as the disease predisposes to renal disease the antitoxin could not be held responsible; all these cases cleared up as soon as the poison was neutralized. No secondary infections occurred after the disease was once under control.

#### *REVIEW OF RECENT EXPERIENCES IN THYROID TREATMENT.*

There are very few drugs in the Pharmacopœia for which it can be claimed that they cure the diseases they are given for in the same sense that thyroid preparations cure myxedema. When the cretin, for example, is subjected to thyroid treatment we find that every one of his functions and tissues is the better for it. Thus his appetite, his digestive powers, and his general tissue-metamorphosis are greatly increased, and he grows amazingly. He generally becomes reduced in bulk at first from losing some of his unhealthy fat, but afterwards he gains weight again, his muscular and connective tissues become healthier and more compact, and his skin softer and moister. His brain tissue also gradually improves in quality, and his mind works more freely and assumes a markedly healthier attitude towards both itself and its surroundings.

It was to be expected that the marvelous efficacy of the remedy in these cases would lead to its being tried in other morbid conditions, and we find that this has been so. Indeed, it would seem as if by this time there was scarcely a disease with any symptoms at all like any of those of myxedema which has not been subjected by some one to thyroid treatment.

It may, perhaps, be of interest to pass shortly in review a few of the more recent papers which deal with the effect of thyroid in some of the diseases of childhood and youth, and to see what measure of success they are able to record.

One of the most interesting and seemingly

most successful applications of the remedy is in dwarfing of various kinds. F. Boullenger and Julius Schmidt, following Hertoghe of Antwerp, have been studying its effects on the growth of non-cretinous children who had not reached the height proper to their age.

Boullenger records nine cases from Bourneville's department in the Bieçêtre. Of these, four were idiots or imbeciles suffering also from obesity. They were given large doses of sheep's thyroid (half a lobe every day or every second day), and although the effect in diminishing their weight was only temporary, the way most of them gained in height was most remarkable. In one the gain amounted to 2½ inches in five months. The other five children were also mostly of defective intellect, besides being much dwarfed in stature. In them the treatment caused some increased growth, but not so much as in the others. This may possibly have been partly due to the fact that those of the latter group were older.

Schmidt's cases were four in number, and were children who, apart from their backward growth, were normal both in body and mind. The administration of thyroid tablets was followed by remarkable increase in height. One case gained nearly 4¾ inches (12 centimeters) in a year.

Hertoghe has recently published a number of skiagraphs of the hands of dwarfs of various kinds, and he has pointed out that the state of the epiphysial cartilages seen in these enables one to give a very confident prognosis as to the possibility or impossibility of renewal of growth under thyroid treatment in any individual case.

There are every year taken into the children's wards of the Charity Hospital, Berlin, a large number of very severe cases of rickets. In spite of every care and all manner of treatment (including phosphorus) nearly half of these children die, generally from bronchopneumonia or enteritis. It occurred to Professor Heubner, after reading Lanz's paper on the connection between the thyroid and the growth of bone, that thyroid extract might influence these cases favorably, and during nine months he gave this a careful trial in sixteen cases.

The result of this experiment, however, was almost completely negative, as he records in a recent paper. No change of any kind could be detected in the morbid condition of the bones. Nevertheless, the mortality of the cases under thyroid was distinctly less than that of those on former methods of treatment

(one-third instead of one-half). This is regarded by Professor Heubner as probably due to an improvement being brought about in the general health of the children, which increased their powers of resisting those complications to which they are generally prone. The complications occurred, but the children seemed to get over them more easily. He thinks that although the thyroid treatment of such cases cannot be claimed as a great therapeutic advance, and has certainly no specific effect on the rickety process, further trial may prove it to be of decided use in suitable cases.

A number of skin diseases have been treated with thyroid with very varying results. One of those in which it seems to have been most successful is prurigo (Hebra). Dobrowsky treated eight cases of this affection with very good results. The children were given no other treatment, and they improved rapidly and very greatly. Within a few days the itching was relieved, the secondary eczema subsided, and the child's general health benefited markedly from the recovered night's rest. The parents were all agreed that no previous form of treatment which they had tried had acted so speedily and so thoroughly. The disease relapsed, however, when the thyroid was discontinued. In 1895 cases were published by Gottstein and by Byrom Bramwell, which seemed to indicate that thyroid preparations exerted a specific effect on tetany. The hopes raised by these communications have not, however, been realized. Many cases of the ordinary infantile form, which occur in rachitic children, and are so commonly associated with laryngismus and convulsions, have since been treated with thyroid by a number of observers. In these there was either no improvement whatever, or it was so slight and so long delayed that one could not but doubt whether it was due to the thyroid at all.

Wolfstein writes an interesting if not very conclusive paper on the case of a girl of twelve, with chorea and very scanty urine, who improved remarkably after being given thyroid tablets (one to three daily). The urine increased in amount at once, and the choreic movements rapidly subsided.

Cases of idiocy of various kinds have been frequently treated with this remedy; but the universal experience seems to have been that practically no improvement of the intellectual powers has resulted. In some instances, however, considerable benefit in the way of bodily growth and lessened obesity has been

observed by Boullenger, Dobrowsky, and others. In those cases which are accompanied by convulsions these are not, as a rule, favorably influenced by the treatment.

Two children with exophthalmic goitre were treated by Steiner with thyroid, without any effect whatever. In nine cases of parenchymatous goitre, however, Dobrowsky found considerable benefit.

From these few abstracts we may gather that if the thyroid substance is not a panacea for all sorts of disease, it is at least a remedy of considerable power, quite apart from its action in myxedema. Its effects are certainly worthy of further careful clinical investigation; and we may hope that a more intimate knowledge of them may lead to its being found a very useful addition to our therapeutic resources.—*Pediatrics*, March 15, 1897.

#### THE THERAPEUTIC VALUE OF NEBULIZED FLUIDS.

F. T. ROGERS, in the *Atlantic Medical Monthly* of March 20, 1897, contributes an article with this title. After describing the nebulizers usually employed he tells us that he can recall numerous cases where the inhalation of the nebulized solution of various antispasmodics promptly relieved asthmatic paroxysms, and with greater ease of application than was possible by the ordinary method of fumigation. Of late years the writer has not seen this disease in his practice, but has had ample opportunity in his own family to test the efficacy of the treatment.

The following solution, nebulized and inhaled, has given the writer the greatest satisfaction:

℞ Antipyrin, 15 grains;  
Pyridine, 1 drachm;  
Sodium nitrate, 2 drachms;  
Tincture belladonna,  
Tincture lobelia,  
Tincture stramonium,  
Tincture ipecac, of each 5 drachms;  
Glycerin, q. s. ad 4 ounces.

Relief has been instant and prolonged, and in two cases of periodic hyperesthetic rhinitis with asthma the solution used in one of the hand nebulizers has proved efficient and has not had the usual loss of efficacy upon repeated trials which so commonly is found with almost any antiasthmatic mixture.

The systematic use of the nebulizer with forced inspiration offers to the asthmatic a double value of exercise and medicine.

Every man, whether engaged in general or

special practise, is likely to be asked at some time to quickly relieve the hoarseness resulting from an acute or subacute laryngitis, and more frequently that due to its chronic form. The use of cocaine in spray followed by the topical application of nitrate of silver or chromic acid is the classical treatment and is the most efficacious in the majority of cases, but Rogers has also gained excellent results by the use of a nebulized fluid containing these drugs, and it has the great advantage of producing quite as much effect on the mucous membrane of the larynx, without the ofttimes distressing spasm which results from applying a caustic solution.

In cases of public speakers, singers, or actors, it has a further advantage—the possibility of auto-application; and when tried just before the effort of speaking or singing is much more efficient than is possible for a topical application to be when made at the office several hours previous.

In acute coryza—that is, in certain cases—the effect the writer has gained from the use of a four-per-cent. solution of antipyrin has been marvelous, and the contractile effect upon the engorged mucous membrane is not only quite as persistent as that of cocaine, but has none of the disadvantages of that drug.

Too many of the abortive forms of treatment for colds depend entirely upon cocaine for their efficacy, and the danger of toxic effects and even the formation of the drug habit are powerful reasons why this drug should not be used.

#### *SOME USES OF CHLORAL HYDRATE IN THE DISEASES OF CHILDREN.*

In *Treatment* of March 11, 1897, SUTHERLAND says there are some drugs the dangers of which are so emphasized that their good qualities are apt to be lost sight of. One of these is chloral hydrate. In this communication it is not proposed to advocate the indiscriminate use of the drug, but to show that when employed in suitable cases, at the proper time, and in doses sufficient to produce a definite effect, it may prove of value. The method of administration will be given in detail in the accompanying histories. It is essential that the drug be absolutely pure, and that the patient be kept in bed and carefully watched when full doses are being employed. When these precautions have been taken the writer has not found any bad effects follow, either immediate or remote. The

appetite has not been interfered with, the intestinal functions have not been disordered, signs of cardiac failure have not occurred, and the drowsiness and lassitude produced by full doses have soon passed off when the drug was stopped. It may be administered alone, or when cardiac complications exist with tincture of digitalis, or in some cases it may be advantageously combined with bromide of potassium or ammonium.

The following case illustrates the effect of chloral in epilepsy: The patient was a girl, aged eight years, who up to the onset of the first fit in August last had enjoyed good health. There was a history of epilepsy on the mother's side of the family, but no other cause could be assigned for the patient's illness. At first the attacks were few in number and of short duration, resembling those of *petit mal*. In the course of the following four weeks the fits increased in number and severity. They occurred both by night and by day, and during an attack the patient was unconscious for two or three minutes, clonic movements were present, affecting the left side chiefly, and sometimes the urine was passed involuntarily. The treatment during this period comprised arsenic, bromide and iodide of potassium, and strychnine, but the fits continued steadily to increase. The patient was then ordered six grains of potassium bromide and six grains of chloral daily, in three doses, and this was quickly followed by a marked diminution in the number of fits. At the end of a fortnight there was a slight increase in the frequency of the attacks, and the dose of the medicine was doubled. This was again followed by a good result, and at the end of eleven days the medicine was stopped. The patient was put on small doses of potassium bromide, digitalis, and arsenic. Almost immediately the fits recurred with greater frequency, amounting to as many as twelve in one day, and increasing doses of the bromide had no effect in checking them. For the twenty-five days before the chloral was commenced the number of fits was 150; for a similar period during which chloral was used the number of fits was 45; and for a similar period after the chloral was stopped the number of fits was 142. The fits had been steadily increasing in number and severity up to the time that the chloral was started, and after it was stopped they again increased until their number and severity was greater than at any previous time. This condition of affairs persisted, although the potassium bromide was increased to sixty

grains daily. As the patient's general condition was very much worse it was decided to try stronger measures. Sixty grains of potassium bromide and thirty of chloral were ordered to be given in three doses at intervals of six hours. On the following five days the same medicine was continued in slightly lessened amount—fifty grains of bromide and twenty-five of chloral. The number of fits decreased rapidly under this treatment, the total during a period of nine days being twenty-four, while the number during the similar period immediately preceding the chloral treatment was ninety-four. As a precautionary measure the bromide and chloral in the above doses were repeated at intervals of three or four days during the next fortnight, but whether this was necessary or not it is impossible to say, as the last fit occurred on the ninth day of the chloral treatment, and a period of four months has elapsed since then without any recurrence. The patient's general health is excellent at the present time.

The following case illustrates the effect of chloral in progressive chorea: A girl, ten and a half years old, developed chorea, which continued to increase in severity for a period of two months. During the first month no advice had been sought, but during the second she had been treated with arsenic, strychnine, massage, with full diet, a moderate amount of alcohol, and rest in bed. At the end of that time the patient was getting worse instead of better. The cardiac action was rapid and somewhat weak, and a systolic murmur of mitral origin was present. The movements were general over the trunk and extremities, the emotional and intellectual centers appeared to be more unstable, and the exhaustion was more marked. More active measures were therefore called for. The amount of stimulant was increased to four ounces of brandy daily, and ten grains of chloral was ordered every four hours. Four doses were given, securing about twenty-four hours' sleep and rest to the patient, and then the chloral was resumed in ten-grain doses twice a day. On the third day after commencing the chloral it was definitely noted that the movements were less violent and less continuous, and that the cardiac action was slower and stronger. On the sixth day the brandy was reduced to one and a half ounces, and the chloral to one dose of ten grains daily. On the eighth day the jerking had practically ceased, and coordinating movements of the limbs could be carried out with

precision. The chloral was discontinued five days later, and the patient allowed out of bed.

The following case illustrates the effect of chloral in the paroxysmal dyspnea of asthma: A boy, aged three and a half years, had suffered from bronchitis and asthma for six weeks, there being severe and prolonged attacks of dyspnea at night. On examination of the chest there were heard numerous catarrhal sounds, and expiration was prolonged and noisy. The breathing during the day was comparatively easy, but at night, usually about 2 A.M., he was awakened by a sudden difficulty in breathing, which persisted for an hour or two, and was asthmatic in character. This was repeated on each of the five following nights, being unaffected by treatment with carbonate of ammonia and iodide of potassium, medicated steam inhalations, stramonium fumes, etc., although the bronchitic signs had considerably diminished. These medicines were then stopped and the patient was ordered ten grains of chloral and five minims of tincture of digitalis twice daily. The following night passed without an attack of dyspnea. The medicine was continued for a week and then stopped, as there had been no recurrence of the asthmatic seizures. During the following fortnight he made good progress, was up and about, and had no attacks of dyspnea. Later on he caught cold, and the breathing again became very labored at times. After the acute symptoms had subsided he was again ordered chloral, ten grains every six hours if required. It was found, however, that one, or at most two, doses daily were sufficient to ward off the acute attacks, and after a fortnight it was discontinued. When seen some weeks later he had not had any further attacks of dyspnea, although the breathing was still asthmatic in type.

These affections resemble each other in being associated with an unstable condition of the nervous system, which manifests itself by some disturbance of function. This disturbance by repetition leads to the production of a vicious habit which it is difficult to cure. It is probable that no single drug is suited to all cases of this description, and in the writer's experience chloral is found serviceable in some cases. The best method of administration would appear to be to give the drug at first in full doses so as to break the habit as quickly as possible, and then in doses sufficiently large to keep the evil tendency in check.

*UNNA'S DRESSING.*

In the Philadelphia *Polyclinic* of March 20, 1897, IDE describes the various uses of Unna's dressing, and tells us what it is and what it can do. Its chief value is for chronic ulcers and sprains or eczematous patches with induration.

Unna's dressing, when completed, consists of a combination of Unna's mixture, or paint as the writer prefers to call it, and gauze bandages in layers, the bandages forming the basis, the paint, which hardens as soon as it becomes cold, impregnating the gauze and being built upon it. The paint is a white mixture which, when cold, resembles very closely the white rubber of which syringes, hot-water bottles, etc., are made. It is of a spongy, elastic consistency, and when heated becomes fluid. The formula according to which it is prepared is as follows:

Gelatin, 4 parts;  
Water, 10 parts;  
Glycerin, 10 parts;  
Zinc oxide, 4 parts.

The gelatin and cold water are put together, in a basin, over a fire, and when the gelatin is thoroughly dissolved in water (there must be no lumps) the other constituents are added, the zinc oxide being added slowly and stirred in thoroughly. The writer always has his made and poured into a quart pail to cool, in which he carries it about, keeping it covered. The zinc oxide is soothing to the skin, especially when the dressing is applied over a chronic eczema. The gelatin gives the paint its adhesive quality, forms its basis, and imparts elasticity to the finished dressing, thus enabling it to exert an even compression. The glycerin has a dehydrating effect upon edematous tissues. Sometimes, as a result of this action, swelling is reduced very rapidly, fluid coming from the tissues and oozing through the dressing. Besides the paint, a supply of gauze bandages and a wide paint-brush are necessary. The gauze bandages can be made from cheese-cloth by drawing threads, and cutting along the line thus made. Two and a half inches make a convenient width for the bandages, and the brush which the writer uses is three inches wide.

The dressing is applied as follows: The limb is scrubbed with soap and warm water, and after being dried is rubbed over with alcohol. When this has evaporated the limb is ready for the dressing. In the meantime the pail of Unna's paint should have been placed over a fire in a hot-water bath, which can be improvised anywhere from a tin or

agate basin. After the paint is melted it is ready to be applied; but do not apply it too hot or the patient will object strenuously. One should test the degree of heat by painting the palm of his own hand. 'Ide always removes the paint, with its hot-water bath, from over the fire when he begins the application, replacing it if it begins to harden before he finishes. With the brush a layer of paint is applied all over the limb, with the exception of the ulcer (if one be present), and over this one layer of gauze bandage is placed in sections, as in any other case, with the one exception that it must be laid flat all the way. There is one rule which must be faithfully adhered to in the application of this dressing, and that is to have no wrinkles at any point in the bandage. Where the bandage begins to wrinkle we must cut it off and begin it flat again. This is why the writer said above that the bandage is to be applied in sections. No section which is more than twelve or eighteen inches in length can be correctly applied. In applying the dressing to a leg he always begins, after the first layer of paint, with a strip of bandage around the foot close to the base of the toes, just as a narrow strip is placed there in applying a plaster-of-Paris bandage to the foot. A second strip is placed around the heel, the middle of which is at the point of the heel, and the ends of which reach to the outer and inner malleoli respectively. Another strip is applied around the heel a little above the first, but overlapping it somewhat. Still another is placed below the first on the bottom of the foot, but overlapping it as did the second. The ends of these other two are brought together at the malleoli, so that they all radiate from the malleoli out around the heel at different levels. In this way the heel is covered in, and then the writer returns to the toes and covers in the foot and leg. In this dressing the bandage is entirely enclosed in the paint after it has hardened, giving it body or basis. A continuous bandage cannot be applied without the production of wrinkles. We can use a roller bandage, however, by pulling it fairly snug with the limb in a horizontal position, the heel resting on a chair or bench, and after as many turns have been made as can be without wrinkles cut the bandage off and start again with the bandage flat. After each section is applied it is painted over with the brush. We must be sure that the bandage fits snugly, making even compression everywhere. If a weak spot is found, where the flesh seems to bulge,

it is to be fortified with a piece of bandage covered with paint. In this manner apply two or three layers of bandage, preceding and following the application of each with a fresh application of the paint over the whole surface. After the last layer of gauze has been applied and painted over, the dressing is covered with a cotton bandage which is left on for twenty-four hours, for the sake of cleanliness, and then peeled off. Under this is found a smooth dressing resembling white rubber, as mentioned above, which is elastic and comfortable and far superior to elastic stockings, each dressing being a perfect fit for the limb to which it is applied. The paint is then washed from the toes and from the skin above the upper edge of the dressing or stocking, and the work is complete. Warm water will remove the paint from the skin or clothing or floor, or anything which is accidentally daubed with it.

The operation requires time and patience, but dexterity is soon acquired. It is a rather dirty job, so that it is well for the operator to have on a rubber apron, and for the floor to be covered by a rubber sheet.

The dressing can be applied to the foot alone, or to the foot and ankle and leg, or to the whole lower extremity; so also to the hand and upper extremity. The upper and lower edges of the dressing must not fit too snugly or end too abruptly, otherwise there will be swelling above or below.

In cases in which there is much edema it is advisable for the application of the dressing to be preceded by massage while the limb is elevated.

Where ulceration is present a wad of cotton is placed over the ulcer, under which is made whatever application may be desired. In such a case when, in the course of the application of the bandage, the ulcer is reached, it is dressed and covered over with a flat piece of cotton and then the dressing is applied over that as if there were no ulcer present. All is left in this condition until the discharge from the ulcer has soaked through the dressing and become foul. Then a window is cut through the dressing, just the size of the ulcer. We begin the window by cutting a very small hole over the center of the cotton which covers the ulcer. This the patient can always locate accurately. The small opening is enlarged by degrees until it corresponds exactly with the size of the ulcer. One may now treat the ulcer as often as indicated, but should not be in too much haste to cut the window. The even compression which presses the parts

surrounding and including the ulcer together and places them at rest does far more good than any application one might be using up to this point. Every twenty-four hours will see the edge of the ulcer nearer its center and farther away from the edge of the "window."

This dressing has superseded the old rubber bandage, which should be thrown to the dogs, for it can but produce (vaso-motor) paresis of the capillaries of the parts over which it is applied. Unna's dressing is far superior to elastic stockings if the patient can afford to have one applied, say once in six weeks or two months.

The most important result which it brings about, from the patient's point of view, is relief from pain and production of comfort from the first. Many a patient has declared to the writer that the first good night's rest he has had for months, and in some cases for years, followed the application of the dressing. For the first day or two it will seem rather tight over the front of the ankle, but it soon stretches a little, the swelling under it disappears, and in two, or at most three, days the patients walk with comfort, provided one cannot induce them to "lie up" and give the limb absolute rest for a time. When the patients can afford to rest it is far better to keep them in bed, or up and dressed with the limb elevated constantly. To this class belong the patients who are treated inside a hospital and in whose cases the most brilliant results are achieved. Those patients who cannot afford to give up all their time to treatment can keep on with their work, and in such cases the improvement is constant and progressive and encouraging, though not so rapid as in the cases which can be kept under control all of the time. The writer remembers the case of a butcher who stood on his feet many hours each day, and yet the improvement was steady. In the case of people who work during the hot summer weather perspiration will soften the dressing around the foot and ankle, and so necessitate its renewal sooner than in cooler weather.

The most important result effected, from the surgeon's or dermatologist's point of view, is the support of the weakened tissues and blood-vessels, especially the veins, and the great improvement in the circulation brought about by the even and elastic compression. The veins are assisted in reassuming their suspended function; feet which have been cold and blue for years, winter and summer, become comfortably warm and

assume the natural pinkish hue; the tissues are dehydrated both by the action of the pressure and the glycerin; fluids which have been exuded into the connective tissue are absorbed and carried away in the circulation, edema disappears, and the swelling goes down, the dressing becomes loose, wrinkles appear in it, and it soon becomes so loose that it must be replaced by another. Sometimes this is necessary in three weeks, but the average time which the dressing has lasted in the author's experience is four weeks. He recalls, however, the case of a hotel clerk with the alcohol habit, tertiary syphilis, slight cardiac dropsy of the legs, with a varicose condition of the veins, with now and then an attack of subacute phlebitis, in whose case he found it necessary to replace the dressing in less than three weeks during hot weather. When the skin is blue and there have been extravasations of blood from the rupture of small veins or venules, followed by ecchymosis and discoloration by blood pigment, the venous blood is sent along, the pigment is absorbed, and the skin becomes white and soft.

The dressing is soothing. The zinc oxide which it contains gives it this soothing quality, and, in addition to the support which it gives to the blood-vessels, it does away with the stretching of the nerves in the walls of the blood-vessels which causes the characteristic burning pain observed in cases of varicose veins.

#### THE TREATMENT OF BRONCHIAL ASTHMA.

The *Boston Medical and Surgical Journal* of March 25, 1897, contains an article by FREDERICK I. KNIGHT devoted to this subject. After discussing the various views of asthma in regard to its pathology he considers its treatment. He thinks the simplest remedies, and those attended with the quickest relief, if relief comes at all from them, are those which are taken by inhalation. They all act more or less by exciting secretion, and most of them by relaxing spasm also. Some act well in one case, and some in another; and those remedies which have most success are usually combinations of various drugs. Nitrate of potassium, stramonium, belladonna, hyoscyamus, and arsenic are found in variable numbers and proportion in most of the powders and cigarettes in the market. One drug or one combination affects one, and another another; and only trial will decide which is best for any particular case.

If no relief comes from such inhalations, then the milder internal remedies may be tried. Phenacetine and other remedies of its class may give relief. Strong coffee or hot alcoholic drinks may suffice. If necessary we proceed to less simple measures, such as the inhalation of ethyl iodide, or the amyl nitrite, or the internal use of nitroglycerin. The latter drug is very efficient in the relief both of spasm and hyperemia. A large proportion of cases recover quickly on the combined use of potassium iodide and nitro-glycerin. Unfortunately the system soon becomes very tolerant of the latter, and the doses have to be constantly increased.

If still more powerful measures are called for, then those agents must be used which have a profound effect in diminishing the irritability of the nervous system. The hypodermic injection of morphine and atropine is one of the best, and will usually give relief, though the writer has seen a case, which always resisted morphine, yield readily to the inhalation of chloroform. The use of chloral, which often gives speedy relief, is to be avoided, if possible, on account of the very depressing after-effects. The writer again warns against the use of any but the simple remedies for the paroxysm, unless absolutely required.

We now come to the treatment of patients in the intervals, to the treatment of the underlying conditions which, singly or combined, cause the attacks.

The first factor to which the writer has directed attention is the condition of the lungs and bronchi. As stated, a previous inflammatory condition exists in many, according to some authorities in a very large majority of cases. In some we have physical evidence of a chronic bronchitis. It is in these cases especially that the potassium iodide gives so much relief, either as an absorbent or as an alkali, increasing and thinning the bronchial secretion. Certain it is that this remedy when properly given relieves and cures more asthmatic patients than any other one. Sometimes, no doubt, the relief comes from its action on enlarged glands which compress the vagus.

The potassium iodide should be given in doses of from five to sixty grains, if needed, for a thorough trial, unless contraindicated. The syrup of hydriodic acid is sometimes useful, but needs to be given in larger doses than those usually prescribed. The dose should be from a dessertspoonful to a tablespoonful.

This is not nearly so efficacious as the potassium iodide.

In case of derangement of the stomach the writer has found the sodium iodide and strontium iodide better borne. He has lately used the latter a good deal, and finds that it is much more acceptable to the patient. All of the iodides should be given largely diluted, on an empty stomach. The writer usually gives them ten or fifteen minutes before meals. The continued use of the nitrites, either alone or with an iodide, when that is indicated, is of great benefit. Nitroglycerin may be used, but the nitrite of sodium has a more lasting effect. The dose of this drug given in many books is too large, one or two grains being usually enough, and large doses dangerous.

In case of emphysema, strychnine is useful; also expiration into rarefied air.

The second factor on the list is pressure on or hyperesthesia of the vagus nerve. As said, potassium iodide may act favorably on enlarged glands which press on the vagus. The same is true of arsenic, which is also a good nerve tonic and is said to act favorably on the bronchial mucous membrane. Practically arsenic has shown itself of great value. Other nerve tonics are indicated, especially quinine, which in large doses may even abort a paroxysm.

The removal of the direct irritant is possible in many cases, and efficacious in preventing the paroxysms, though hyperesthesia of the nervous system may be a prominent symptom. Feather beds, animals, kerosene lamps, arsenical wall-paper, various kinds of dust, and many other objects, when found to be excitants, may be easily removed; but others cannot be, and yet it may be possible to remove the patient from them, as in the asthma of autumnal catarrh or other less defined climatic or atmospheric conditions. Certain regions of this country are known to be exempt from all of the symptoms of autumnal catarrh, asthma included.

In other cases the atmospheric condition which provokes the attack is not so well defined, and relief may be obtained only after repeated changes. The slightest change in location will sometimes give relief. More patients get relief by going from the country to the city than from the city to the country. A curious feature of the immunity of location is that in time it often fails, and another change is necessary. The author recalls the case of a physician who changed his residence and practise several times during his life, on

account of asthma, and who finally got relief by going back to the place from which he started.

In making any change consideration must, of course, be paid to the probable effect of the climate on other factors—for example, on the condition of the lungs and bronchi and on the nervous system.

Of peripheral origin of reflex irritation the nasal region furnishes a good many cases, so many that the digestive and other important regions have recently been too little investigated. The nasal polyp is easily recognized, and so usually are other morbid conditions which are likely to set up reflex action. Contact of a turbinate bone with the septum may be a source of great irritation, less frequently chronic disease of the turbinates, tonsils, pharyngeal-adenoid, etc. The whole naso-pharynx must be put in as healthy a condition as possible.

The digestive derangements have been in recent years far too little considered. Indigestible food, especially when taken at night, is often the cause of an attack; though other factors may be present, it is this added irritation which determines the paroxysm. The digestive tract is so much under our control that it is very important to regulate the quality and quantity of food and time of meals, and perhaps also to treat some evident morbid condition. The intestinal tract must be investigated, especially for parasites. The sexual system and possible trauma must be considered.

No study of an obstinate case is complete without the consideration of toxemia. Lead and arsenic should be sought, and especially should the lithemic condition be looked for. An antilithic diet, regimen, and medicine will relieve many otherwise incurable cases. The same is true of the appropriate treatment of malarial cases. In cases of renal dyspnea due to uremic intoxication there is sometimes an apparent increase of suffering, due perhaps to spasm of the bronchi, as indicated by sonorous râles; but it is better not to consider these cases under the head of bronchial asthma such as we have been considering.

It will be seen from this brief sketch that many morbid conditions may be concerned directly or indirectly in the production of a case of bronchial asthma, which act singly or combined, and that the treatment should be directed towards the removal of as many as possible of these conditions. The result will be more satisfactory the nearer we get to a removal of all of them.

The more of these factors we can diagnose the simpler may be our treatment. Grand combinations of many drugs either for inhalation or internal use are to be avoided unless single remedies fail. Patent and proprietary medicines, and treatment of patients at a distance without examination for differential diagnosis, must naturally be compound, including everything known to be "good;" but when a physician can have his patient under observation this can often be avoided. In conclusion, the influence of climate is often very subtle, yet if we proceed on the same lines as have been suggested for medicinal treatment, of considering what factors we may influence by change of climate, we may yet often guide a patient successfully. Can we remove him from some direct irritant, as in the hay-fever cases? Shall we find a climate which will fortify or calm a hyperesthetic nervous system? Or shall we (which is perhaps oftenest required) put him in a climate which will act favorably on his bronchial inflammation? If we wish to do the latter, a dry, elevated region is indicated if the bronchitis is moist, but a warm, moist climate will probably be better if the bronchial mucous membrane is dry and irritable. As in all other means of treatment the nearer we get to an exact diagnosis of the exciting and underlying causes of asthma, the more intelligently and successfully will we be able to advise in regard to change of climate.

---

*SIXTEEN YEARS' EXPERIENCE IN THE  
TREATMENT OF SYPHILIS BY THE  
HYPODERMIC INJECTION OF  
BICHLORIDE OF  
MERCURY.*

In the *New Orleans Medical and Surgical Journal* for April, 1897, DABNEY contributes a valuable analytical paper on mercury by the hypodermic needle. In its close he weighs the objections and advantages of the treatment by subcutaneous injections.

The objections raised against the method are: (1) Unnecessary pain; (2) subcutaneous infiltration; (3) large indurated and painful swelling; (4) inflammation; (5) abscesses; (6) stomatitis; (7) pyalism; (8) disturbances of circulation and respiration.

That pain does occur in some cases cannot be denied; but as a large majority of syphilitics suffer from partial or complete cutaneous anesthesia, this objection holds good but in comparatively few cases.

In hyperesthetic cases it is hardly admissi-

ble and cannot be recommended. In sixteen years' experience the writer recalls but three cases where pain acted as a deterrent factor—one boy and two neurotic women. In every other case the patients maintained that the pain was less objectionable than the taste of medicines. The addition of alcohol, recommended by some, adds much to the pain and detracts from the efficacy of the bichloride.

Injection of morphine before or in conjunction with the mercury is to be condemned for two reasons: because it in no wise alleviates the pain, which does not reach its acme for three or four hours; and it may lead to the opium habit—highly probable in this class of patients.

What objection there can be to cellular or subcutaneous infiltration the writer is at a loss to understand. We use the loose cellular tissue as a storehouse whence the mercury is slowly given off. The indurations are painful when roughly handled, just as those of vaccination are, though he has yet to hear that objection raised to preventive measures of smallpox, and why should it be a valid objection to curative measures of pox? When the needle is not plunged deep enough, quite an area of inflammation is, in some instances, set up.

It has been the writer's misfortune to cause two shallow abscesses, but in each instance the abscess was due to neglect of asepsis, and not to the injection of the greatest of all known antiseptics. He has also broken off a needle in a man's arm. This needle caused no inconvenience whatever.

So far he has seen no untoward circulatory or respiratory disturbances, unless the increased pulse-rate and the rise in the cutaneous temperature which always accompanies the continued use of mercury could be classed under that head. Ptyalism and stomatitis may unquestionably be produced by the administration of mercury in any manner; but he happens never to have witnessed those lamentable effects in any case treated hypodermically; whereas he has rarely seen a case treated by other methods without them. At Hot Springs tincture of myrrh for the mouth and gums is almost as important a part of the treatment as the inunction of mercury and the large doses of the iodide.

The advantages claimed for this method are: (1) accuracy of dose; (2) exactness in intervals between doses; (3) rapidity of action of medicine; (4) small amount of mercury and the short time needed to effect a cure; (5) the constant, never-ceasing effect of the mer-

cury day and night; (6) the personal supervision of the physician; (7) the certainty of the patient getting the right medicine, of its being properly administered at regular stated intervals, and of his inability to get the prescription refilled, or to give the knowledge to a friend, or sell it to some charlatan; (8) profit to the physician and economy to the patient on account of the saving of the drug bill of four years. The doctor with this method is sure of two very important things: his fee, and his patient's gratitude for his speedy cure—quick delivery, so to speak; (9) absence of gastro-intestinal disturbances; (10) last, though not least, quick diagnosis in questionable cases.

The *modus operandi* is as follows: First, care must be taken to avoid all joints, glands, and blood-vessels. The best sites for the injection are the chest-walls, back, gluteal region, and the upper and outer portions of the arms. The site chosen should be well soaped (green soap) and washed and dried, then rubbed briskly for a few seconds with alcohol. The needle and syringe should be immersed in hot water before each injection. The needle should then be plunged quickly through the skin and well into the cellular tissue, care being taken to avoid invading adipose or muscular tissue (though some authorities advise deep muscular injection). The injection should be very slowly made, care being taken not to use too much force. As soon as the bichloride solution comes in contact with the albuminous serum, the soluble mercuric chloride immediately becomes the albuminate, which is not very soluble, and herein lies the efficacy and safety of these large doses of this highly corrosive poison. By means of this chemical metamorphosis we can store up in the cellular tissue mercury that can be taken up by the secretions and distributed throughout the entire system in such dilution as to do no harm to the most delicate structure. How different is the result, say, when given by the mouth in pill or solution. Here the medicine coming in contact with the daily ingesta may form insoluble combinations and pass through the bowels as an inert mass, or it may, through the presence of malic, lactic, citric, or other acid, form highly soluble or irritant salts, and thus bring on free catharsis, and be swept away before reaching the systemic circulation. One of the most striking effects of the hypodermic injection of the bichloride is the way it tones up old, broken-down syphilitics. This tonic effect is at times so strik-

ingly shown as to cause surprise to the patient as well as to the physician.

This treatment does not entirely do away with the iodide of potash, for this remedy, though it never cures but only subdues, may after be used in conjunction with the injections, especially where the throat, brain, or spine are involved. Wherever mucous patches occur he applies the solid argentic nitrate. Sulphate of copper crystals are highly recommended by many authors, but they are not as quick nor as efficacious as lunar caustic.

The writer feels that he has in this treatment a scientific, accurate, rapid, and absolutely safe method of mercurializing his patients and of keeping them under the never-ceasing influence of mercury as long as a vestige of syphilis remains. He no longer dreads to face a syphilitic seeking his advice, for he feels absolute confidence in his ability to cure him in a definite time.

---

#### THE PRE-DIAGNOSTIC TREATMENT OF GRAVE ABDOMINAL DISEASE.

G. SMITH in *Treatment* of March 25, 1897, writes on this very important practical topic and points out that acute abdominal disease cannot always be diagnosed offhand. Often the diagnosis must wait, but rarely is the treatment permitted to wait; and this treatment, directly aimed at the relief of symptoms as it is, may succeed only in aggravating the disease, while it makes diagnosis almost impossible. It is true that with the general public the relief of suffering comes before the cure of disease, and the action of the kindly physician who, seeing pain, relieves it with his morphine syringe, will never be severely condemned. If the patient is thirsty he will have ice to suck; if his heart's action is feeble and rapid he will have suitable medicines and drinks administered by the mouth.

Then comes in the surgeon, who is requested to cure the disease. Now for surgical purposes some sort of diagnosis is desirable; and diagnosis in grave abdominal disease is simply impossible if the patient is narcotized. Also operative treatment is dangerous and difficult in these cases, and it does not add to the too slender chances of success if liquids have been poured into a perforated stomach, or the intestines have been either started into furious action by iced fluids drunk or paralyzed by morphine injections.

What then is to be done? Is it possible in such cases to pursue a course of treatment

which will certainly do no harm, but will probably do good, and which will not obscure the signs and symptoms, but will rather help in their evolution and interpretation?

We will suppose a patient in ordinary health up to the moment of attack; the physician finds him in bed suffering great pain and with the ordinary symptoms of serious abdominal disease. It may be impossible to say whether it is simply colic—intestinal, renal, or biliary—or some grave condition such as obstruction or perforation of a viscus, or even extravasation of blood. The shock may be caused by pain and fright; it is very like true collapse such as might be produced by peritoneal diffusion of the contents of a perforated stomach, or of a periappendicular abscess, or by the rupture of a tubal pregnancy.

The first thing to be done under these circumstances is to administer an enema containing an ounce of brandy or whiskey. The brandy is best given in milk, which the rectum tolerates, and about three ounces of milk is enough. Before giving it the rectum is explored with the forefinger, and the evidence, positive or negative, thus afforded is treasured up towards the diagnosis. As the finger is withdrawn the nozzle of the syringe is inserted, almost by the same act as the examination is made, and the enema administered.

Then the patient is swathed in hot blankets, one being rolled round each leg, and one, pulled under his back, is rolled round his chest. Hot-water bottles are packed around limbs and body. The abdomen is left to be covered separately by some light woolen wrap, which can be easily removed so as to permit of examination of the surface. The attendant now sits down by the bedside of the patient to watch him and to complete the diagnosis; and he ought scarcely to leave his side till the diagnosis is complete.

Meanwhile the alcohol and the warmth are doing their beneficent work. The pulse improves; color comes into the patient's cheeks and lips; excitability and nervousness are diminished; pain is probably lessened; and soon the surface is covered with warm perspiration. No single therapeutic measure with which I am acquainted does so much good in the early stages of grave abdominal disease as rectal injection of alcohol. It is indeed a fortunate thing for the patient that, while the whole of the rest of the intestinal tract is paralyzed and useless, the rectum still retains its power of passively absorbing liquids.

The surgeon sitting by the patient intently

watches the evolution of signs, and uses such aids in palpation, percussion, and especially in auscultation, as he thinks proper. Every individual sign is noted and kept in mind as it is evolved; and it will be surprising if, at the end of half an hour, their aggregation does not permit of a diagnosis being made sufficiently accurate for exact treatment.

The general behavior of the patient is important. In spasmodic colic—intestinal, renal, or biliary—the patient makes a great fuss; he is in acute pain, and he lets every one know it, calling out and rolling and twisting about in all directions. Very differently behaves the patient with visceral perforation; he makes little fuss and no complaint; he keeps his body rigidly still; his arms only does he move, bending and stretching and raising them, while he rolls his head wearily from side to side. Between the two are the intestinal strangulations with their special signs. The condition of the parietes as to tension and distention, spasm or relaxation, is carefully noted, and the movements or quiescence of the intestines are observed. If the intestinal muscle is acting violently there is no perforation, for intestinal paralysis is one of the first effects of diffusion of fluids in the peritoneum. All over the abdomen there is silence to auscultation, save at the seat of perforation, where there are rare and mysterious blowing or rushing sounds. In the parietes we must distinguish between tension and distention, between hardness from reflex or voluntary muscular spasm and hardness from physical stretching, giving each variety its true meaning; and intermittently we percuss, especially over the region of the liver. If there is not much distention, abrogation of the liver dulness is almost pathognomonic of perforation and escape of gas from a hollow viscus or from rupture of an abscess which contains gas—such as an appendicular abscess. If there is much distention, so that bowels may get between liver surface and parietes, this sign is of less value. But the abdomen takes long to distend; the parietes get very tense before they stretch in acute disease.

The sign revealed by auscultation may be of great value. The disk of the phonendoscope is laid on the parietes and moved about from place to place, while sounds are patiently listened for. It must not be forgotten that intestinal sounds are not like cardiac or pulmonary sounds, repeated rhythmically so many times a minute; on the contrary they may occur only at long intervals, and recur with no measurable regularity. To

attempt to describe these sounds would be to go beyond the scope of this paper. It is always possible to be certain of the natural and diffuse sounds in colic; of the exaggerated local and rushing sounds in obstruction; and of the curious general silence with rare and remote noises in perforation. They must be heard again and again, and listened to long, before one can be certain of their meaning.

We shall now be in a position to say whether it is colic or dangerous disease. The final diagnosis may be made with the help of chloroform. The patient is given a little chloroform to inhale; if it is simple colic he greedily inhales it, delighted with the relief it gives; in a few minutes the marked improvement of the patient's condition will almost prove the diagnosis. In perforation or strangulation the patient is not greedy to inhale the chloroform; it may increase the nausea, and it does not cause marked improvement in the symptoms. When we have decided that the disease is no more than colic we may at once give a full dose of morphine and begin the proper treatment, of which no more need here be said. By the time that half an hour has passed the diagnosis will have gone so far that the decision for or against operative interference will have been made. Preparations for operation are rapidly made by assistant and nurses, while the surgeon stays by the patient's side to continue to read the signs and make the diagnosis complete. His aim will now be chiefly to locate the mischief so as to know where to make the abdominal incision. It matters little to the surgeon what has to be done; it matters greatly to the patient that it should be done quickly and deftly; and one essential of speed and excellence of opening is that the parietal incision shall be well placed.

It will be seen that the author places in the front these items of advice: Avoid morphine; give nothing by the mouth; give an enema containing a full dose of alcohol; and apply heat to the patient's body. Then we sit down and watch. As shock passes off the natural evolution of special signs comes on. These we carefully and patiently observe by sight, touch, and hearing, and their interpretation is the diagnosis. But their evolution being slow and complex, and their meaning often obscure, we must wait while they repeat themselves again and again, and not leave the patient's side till solid reasons have been found for a definite line of treatment.

#### TREATMENT OF ACUTE MYELITIS.

JAMES TAYLOR writes on this topic, which is seemingly dealing with a barren therapeutic field, in *Treatment* of March 11, 1897. He thinks that in such a condition the object of treatment will be to prevent, if possible, the extension of the mischief upwards or downwards from its original focus, and also to prevent any of the paralytic effects of the disease from becoming a danger to life. The effects, which are apt to be troublesome and dangerous even if no extension of the original inflammation takes place, are: (1) trophic disturbance; (2) retention of urine, and cystitis leading to kidney affection; and (3) in a minor degree, constipation and abdominal distention. With reference to the first of these it should be recognized from the commencement that very serious trophic disturbance may arise from very slight pressure, and in some cases apparently arises spontaneously. A careful watch must be kept for the slightest appearance of any such change, and the parts on which pressure comes must be carefully and frequently sponged and spirit rubbed into them with the palm of the hand. It is essential in every case of acute myelitis that a water-bed, or at least water-pillows, should be used, and that great care should be taken to avoid anything likely to irritate the skin or permit an abrasion. It has been recommended that the patient should assume the prone position in order to prevent the spinal cord from being dependent. In the acute stage of the illness, however, such treatment is seldom, if ever, possible. It is often most useful in the later stage when the fever and malaise have subsided, and it is of special value if any bed-sore has unfortunately developed. If such a position is advisable it is best to have a prone couch close to the patient's bed, to which he can without inconvenience be occasionally moved for an hour or two at a time.

The second inconvenience, and even danger, which is apt to occur at an early stage is in connection with the loss of control over the bladder. Retention of urine takes place, and the patient may first become aware of the fact that everything is not in order by the dribbling away of urine, the sequel to overdistention. Such a condition is usually spoken of as "overflow incontinence." It is sometimes said that even in these cases cystitis does not occur except as a result of infection by a dirty catheter. This, however, is not correct, for cystitis may occur in certain cases of acute myelitis even before a

catheter is passed. Nevertheless it is of the utmost importance that extreme care should be exercised in regard to the condition of the catheter, and not only should the urine be drawn off, but the bladder should be washed out by means of a solution of a mild antiseptic like boric acid. After a time, if the case goes well, the bladder is likely to regain its power of contraction, so that it is able to empty itself wholly or, more usually, partially, not in obedience to the volition of the patient, but reflexly. Such a condition is spoken of as "reflex incontinence" to distinguish it from the overflow incontinence already alluded to as occurring earlier. Even in this condition it is desirable that the catheter should be passed at least twice in twenty-four hours, and also that the bladder should be washed out, for in probably every case it never empties itself completely. In the stage of complete retention the catheter should be used once in every six or eight hours. It may be occasionally necessary to use it even more frequently.

The condition of the bowels is a third source of possible inconvenience. There is always considerable difficulty in getting them to act, and there may ensue an inconvenient degree of abdominal distention. The constipation in many cases seems to be diminished by belladonna—one-sixth or even one-fourth grain of the extract twice daily, in pill. Enemata are often ineffective, because they are not retained; but glycerin is more efficacious than the fluids, which have to be given in larger quantity. For the distention gentle rubbing of the abdomen may be done. Purgatives also are useful in relieving the distention, but in some cases it may be necessary to pass a tube through the rectum into the colon.

Can anything be done by drugs to allay the inflammation or to prevent it from spreading? Ergot and belladonna have both been recommended, and their use in some cases has been followed by improvement. Strychnine is certainly contraindicated while the condition remains acute. Absolute rest, light fluid diet, careful attention to the skin, the bladder, and the bowels, really sum up the treatment in the acute stage of acute myelitis. Any form of counter-irritation is inadmissible, because of the danger of starting trophic disturbance.

When there seems to be no further danger that the inflammation is extending, iron and quinine may be given in small doses, especially if, as is often the case, some anemia is asso-

ciated with the myelitis. The diet also may gradually be made more liberal, and a little stimulant may be added if the patient takes his food badly. Counter-irritation to the back may now also be employed, and by far the best method to use is that by means of the Paquelin cautery. Several pricks should be made each day by means of the heated round blade on each side of the spine, at and about the level at which the sensory impairment stops.

The reflex action, if no extension to the lumbar enlargement has taken place, will now have returned, and it quickly becomes excessive. It is often necessary to strap the limbs with soft voluminous bands such as knitted woolen shawls, and pillows will sometimes have to be placed between the limbs to prevent them touching and perhaps abrading each other. But as a voluntary action returns the reflex movements become less, and when this stage has been reached massage and passive movements are of considerable use in improving the nutrition of the muscles and in strengthening the various movements in the limbs. As soon as the patient is able to walk a little great care will have to be taken to prevent him from overdoing the exercise. The bladder trouble not infrequently persists even after the patient is able to walk well. When this is the case strychnine in small doses has a very distinctly beneficial influence, but it should be used cautiously on account of the possibility that it may induce a recurrence of the excessive reflex action. In some cases arsenic and chloride of aluminum seem to have a tonic influence on the affected nervous structures, and it may be stated generally that the degree of recovery in many cases of acute myelitis is far greater than one would expect from the nature of the disease and its apparent extent at the onset of the attack.

---

#### ON THE ACTIVE PRINCIPLE OF RHUS TOXICODENDRON AND RHUS VENENATA.

FRANZ PFAFF concludes in a very interesting paper in the *Journal of Experimental Medicine* for March, 1897, that as to the rational treatment of Rhus poisoning, it is to be noted that the poisonous oil, as we have already repeatedly stated, is non-volatile. It is very sticky and will cling persistently to parts which may have become contaminated with it. It oxidizes in contact with air and is transformed into a solid resin. But this proc-

ess is a very slow one. This resinification of the oil may be hastened by heat and alkalis, even by a solution of carbonate of sodium; but still the process remains a very slow one. The metallic compounds of the oil, after decomposition, leave again the oil with all its irritant properties. The poisonous oil is soluble in most of the common solvents and fatty substances, but is insoluble in water.

From all the chemical properties just enumerated, the rational indication in a case of Rhus dermatitis would be to get rid of the poisonous oil that may still be on the skin of the affected person as quickly as possible, no matter in what stage the eruption may be.

This can be done by vigorously washing the affected and exposed parts with soap, water, and scrubbing-brush—that is to say, mechanically. As the active principle is very soluble in alcohol and gives with lead acetate a precipitate which is nearly insoluble in alcohol (the copper and iron compounds are also easily obtained as precipitates), other processes may be employed to remove the oil. The exposed parts may be washed repeatedly with fresh quantities of alcohol and a scrubbing-brush; the poisonous oil would be thus removed in alcoholic solution. Or still another way of operating would be to wash the exposed parts with an alcoholic solution of lead acetate. In this case the poisonous principle would be first transformed into its insoluble lead compound and then washed away with alcohol. The washing must be done thoroughly when alcohol is employed, as otherwise the alcohol would only help the spreading. The nails have to be cut short and also perfectly cleaned with the scrubbing-brush. Oily preparations, or anything which dissolves the poisonous oil, if used and not immediately removed, would only spread the poison, giving it a larger area on which to work. This spreading was well seen in one patient's case. The vaselin ointment used in the treatment dissolved the oil which adhered to the point of application, and thus caused the spreading of the eruption. That the proposed treatment does not cure the already inflamed parts is self-evident.

How can the commonly accepted idea be explained that poisoning may occur without actual contact with the poisonous plants when the active principle is a non-volatile substance? The activity of toxicodendron in minute traces may make it possible for a few pollen grains of poison ivy to cause skin eruption; and the few cases of action at a distance, which are so often quoted, may

conceivably be thus explained. But in the writer's opinion it is more than doubtful if ever a case of ivy poisoning has occurred without direct contact with the plant or some article which has been in contact with the plant. The long latent period of the eruption in some cases may obviously render mistakes extremely easy as to the occasion when contact with the plant really occurred.

#### PREPARATIONS OF IRON IN THE TREATMENT OF CHLOROSIS AND ANEMIA.

At a recent meeting of the Société de Thérapeutique, a report of which appears in *Le Progrès Médical* of April 3, a discussion on this subject was opened by M. Bardet, who said that the majority of authors regretted that it had been generalized by including in it the treatment of various forms of anemia, instead of limiting it to chlorosis. M. Bardet, however, was of the opinion that when it was necessary to employ iron preparations the special treatment became the same in chlorosis as in simple anemia. He considered it difficult, in a discussion on therapeutics, to separate chlorosis, properly so called, and the various forms of anemia. It has been well said that in the treatment of anemia the principal indication was to suppress the cause and then the anemia would disappear. But, he said, it was none the less true that the iron treatment of anemia played a great part in therapeutical intervention, and consequently it would be prejudicial to leave out anemia in a discussion on iron treatment. Moreover, he questioned whether it was correct to profess to be able to remove the causes, which were more frequently connected so closely with the effects that it was impossible to make out the precise limits between the cause and the effects.

The value of different preparations of iron had been the subject of much discussion. Some authors had advocated the use of the free metal; others had recommended the iron salts; others, again, had given the preference to organic preparations, and among these several authors had adopted exclusively the albuminates. M. Bardet was convinced that all these discussions were useless, and that all iron preparations were good or bad according to the particular cases, not forgetting that everything depended on the absorption, and that this was itself dependent exclusively upon the digestion; and as this was a most complex phenomenon, varying according to the individual, certain preparations might

prove good for some persons and bad for others. All iron preparations might be tried, and the one that was tolerated by the patient would be the right one.

With regard to the different preparations of iron, M. Bardet preferred hemoglobin, although there was another preparation which he thought should not be forgotten in a discussion on this subject. This was glycerophosphate of iron, which he thought was destined to take an important place in therapeutics. Up to the present time it had not been easy of employment, owing to the difficulty in keeping it. M. Bardet, however, had made use of this salt in anemic persons by combining an organic iron preparation with the glycerophosphate of iron and particularly with the phospho-glycerate of lime. He had employed these combinations for the past three months with the best results.—*New York Medical Journal*, May 1, 1897.

#### MALARIAL HEMATURIA.

In the *New York Polyclinic* of April 15, 1897, KILPATRICK writes on this important subject as follows:

The real cause is undoubtedly malaria, and in this section (Georgia) it is confined strictly to the white race. He has never known a negro to have it.

At the onset the writer finds the symptoms to be as follows: The patient is taken with a chill, not very decided in every case, and of short duration. He may be attending to his duties and is not necessarily confined to bed. At the expiration of these chilly sensations there is a rise in temperature ranging from  $101^{\circ}$  to  $103^{\circ}$ . About this time he desires to micturate, the urine being of a dark coffee color, or perhaps a cherry red, and sometimes very copious. The quantity voided is about half a pint, often less. The patient does not seem to experience any pain while voiding urine other than a dull, aching sensation in the region of the kidneys. The fluid has been submitted to a microscopical examination and found to contain no blood-corpuscles. There is often at the onset intense nausea and vomiting, and at the expiration of six or eight hours, sometimes earlier, decided jaundice and cold feet.

The indications are for purgation and diuresis. The author gives large quantities of warm water; lets the patient drink all he can, and so distend the stomach as much as possible. After a thorough washing in this way he lets him sip very hot water to relieve

the irritated stomach, and places a mustard plaster over the epigastric region. He then receives an enema consisting of a quart of warm water with the yolk of one egg and ten drops of spirits of turpentine. Hot-water bottles are placed to his feet. If vomiting is not controlled by this time, he gives, in capsules, half a grain of cocaine hydrochlorate every half-hour till a grain and a half is taken. The purgatives and diuretics seem to control the temperature. As a purgative he gives from ten to twenty grains of calomel with the same amount of bicarbonate of sodium every hour till he gets copious, dark stools. As a diuretic he uses potassium acetate every half-hour to every hour till the urine resumes its normal color. When this occurs he feels that his patient is safe.

The after-treatment consists in giving three times a day ten drops of a mixture of tincture of nux vomica and Fowler's solution, equal parts. If the patient is very anemic, he adds tincture of chloride of iron. After the skin clears up he gives three or four grains of quinine bimuriate three times daily.

The duration of this affection is very short, but it requires prompt and heroic treatment. The main point is to keep the kidneys and bowels acting freely. His reasons for not using quinine are that it often keeps the stomach upset and that it is so slowly assimilated there is not sufficient time to wait for its action. He uses no hemostatics as the urine, no matter how red, does not contain blood-corpuscles unless there are organic lesions about the kidneys or the urinary tract.

The temperature and circulation will take care of themselves if the system is rid of its engorgement of cells broken down by malaria.

#### BRONCHOPNEUMONIA OF CHILDREN.

A practical article on this topic is contributed to the *Northwestern Lancet* of April 15, 1897, by CARLAW of Minneapolis. After considering the disease from various standpoints he turns to the treatment and gives useful advice. He admits that there is as yet no specific treatment, but thinks much may be done for the comfort and guidance of these little sufferers in their struggle for life. First and foremost is the hygienic management. The child should be placed in a good-sized room, where there are ample facilities for admitting air and sunlight. The cot or bed should not be placed against an outside wall, if the season be winter. Unnecessary furniture would better be removed. The clothing of the cot

should be light, clean, and warm; sheets may be discarded for soft flannel blankets. The child should be attired in flannel nightgown, preferably of the "combination" variety. The bedclothing and nightclothes should be kept clean, and changed and aired daily.

The temperature of the room should be maintained day and night from 68° to 70° F. Free and constant ventilation should above all other things be obtained, and its maintenance be rigidly insisted upon. This is best accomplished by lowering a window from the top, which will allow the free ingress of fresh air. If a fireplace be in the room and in working order, it is well to keep a fire in it, as it is one of the best means of ventilating and carrying off impure air. The air in the room may be kept moist to advantage, preferably with the steam of boiling lime-water. The attendants on coming in from the outside air, if the weather be cold, should warm themselves before going near the patient. The physician should do likewise, and should warm his stethoscope and hands before examining the chest.

Attention to the countless little things which promote the comfort of the little one is most important, such as changing the child's position frequently, drying its skin with a soft warm towel, keeping the mouth clean, etc.—or, in other words, "good nursing." In many places among the poor such hygienic measures cannot be carried out as well as we would desire, but the best possible under the circumstances should be insisted upon, and we must always remember that medicine can never take the place of hygienic treatment.

For those who are artificially fed milk is the ideal food; it should be given with lime-water. It is best to feed the child at regular intervals, say every two hours. Albumen water, made by mixing the whites of two eggs with a pint of water and adding a little salt, will be found very nourishing and may be given ice-cold. Older children should have animal broths in addition to milk. Cold water should be constantly on-hand and the child encouraged to drink freely. Stimulants in severe cases should be given from the first, and good rye whiskey is one of the best forms to administer. It may be given in the egg-albumen water, and its dose will vary with the age of the patient and severity of the disease.

In mild cases a well fitting cotton-batting jacket, lined on the inside with cotton flannel and on the outside with oil silk or oiled muslin, will be sufficient. The chest may be

first rubbed with some stimulating oil or liniment, such as two drachms of oil of turpentine and one drachm of the stronger solution of ammonia, in two ounces of soap liniment. In severe cases where the cough is painful there is nothing that will give the relief and satisfaction of the time-honored flaxseed poultice.

As little medicine as possible should be given, and all medicines of a depressing nature avoided. The bowels may require to be moved at the onset, which may be done with small doses of calomel, but we must be careful in regard to purgatives, especially in cases following measles, as they are apt to set up gastro-intestinal complications.

In the early stage, if the cough is dry and the bronchitis troublesome, as indicated by a preponderance of dry râles, some alkaline cough mixture, as one or two grains of nitrate of potash, with ten or fifteen minims of syrup of ipecac, given in equal parts of liquor ammonii acetatis and syrup, or fluid extract, of licorice, to one teaspoonful, for a child two and a half or three years old. Such cough mixtures should be given freely diluted with water.

When the cough is loose and moist râles more abundant, the ammonium salts will be found efficient. Some prefer the chloride, others the carbonate. When the acute symptoms are present the carbonate is perhaps more indicated. This salt is not only an efficient expectorant, but also a valuable cardiac and respiratory stimulant, all of which actions are indicated in the treatment of bronchopneumonia. It can be combined to advantage with vinegar of squills and given in the fluid extract of licorice, which disguises its taste most efficiently. The dose will vary with the age; for a child fifteen months or two years of age, one grain of the carbonate with fifteen minims of *acetum scillæ* given every two hours will generally suffice. Later in the disease the chloride may be substituted, which has an alterative effect and tends to lessen the secretions of the bronchial mucous membrane, and during its use digestion usually improves.

Strychnine is also a valuable respiratory stimulant and heart and systemic tonic, and is of undoubted value. In desperate cases its judicious hypodermic use is superior to all other known remedies, and has many times turned what seemed a hopeless case to recovery. In all such cases it is the remedy *par excellence*.

Cough rarely requires treatment, and should not be stopped, as it is the only way a child

has of cleansing out its bronchial tubes and preventing collapse.

We must be guarded in giving opiates to allay pain. As a rule flaxseed poultices will generally be found sufficient; if not, compound tincture of camphor may be added to the cough mixture, or Dover's powder may be given.

If there is dyspnea due to obstruction of the bronchial tubes from accumulated mucus, an emetic should be given. In weak and debilitated children these should be used cautiously. Ipecac is perhaps the safest and most frequently used emetic. In older and stronger children turpeth mineral by the mouth, or apomorphia hypodermically, are recommended. When the dyspnea comes in paroxysms, and is not due to obstruction of the bronchial tubes with mucus, there is no treatment equal to the hot bath. The temperature of the water should be about 100° F., and the child allowed to remain in the bath for ten or fifteen minutes, then wrapped in a woolen blanket.

As a rule children bear high temperatures without the rapid prostration observed in adults. Even a temperature of 104° or 105° F. does not always call for antipyretic drugs. The fever of bronchopneumonia seldom calls for special treatment, but should it do so there is nothing better than the general bath with water at 100° F., gradually lowered to 80° F. or lower. The bath may be repeated several times daily if required. The coal-tar antipyretic drugs must be used with caution. The bath is much more to be preferred than dosing with antipyretic drugs, as it not only lowers the temperature effectively, but also acts as a general tonic, and tones up and refreshes the child, and is usually followed by refreshing sleep.

Collapse requires bold and energetic treatment, hypodermics of ether, brandy, and strychnine. The latter may be added to the brandy or ether, whichever is chosen. A douche of cold water to the nape of the neck will usually cause violent inspiration followed by vigorous coughing, even though a high degree of carbonic acid poisoning be present.

Another way of treating these cases is by mouth-to-mouth inflation. When the breathing becomes improved the child may be wrapped in a sheet wrung out of hot mustard water, within a flannel blanket. Plenty of fresh air should be allowed. Some recommend the child being wrapped in a sheet wrung out of ice-cold water, a flannel blanket on the outside, which stimulates the nervous

system and improves very markedly the general condition.

In cerebral cases the main remedies to rely upon are the hot bath, chloral by the rectum, or the bromides and hyoscyamus by the mouth.

Careful regulation of the feeding during convalescence must be observed. If hypersecretion of the bronchial mucous membrane continues oil of turpentine will often be found beneficial, or syrup of the hypophosphite of lime. Later, cod-liver oil and iron will be found of service, but before these are given we must see that the digestive organs are able to take care of them; if not, they had better be preceded by a short course of muriatic or nitro-muriatic acid, with tincture of nux vomica in some of the vegetable bitters, as the infusion of calumba.

Cod-liver oil may be used by inunctions in young infants to advantage. The syrup of the iodide of iron is perhaps the best iron preparation to use. If the bronchial glands are enlarged they are best treated with muriate of ammonia or syrup of hydriodic acid.

Caution should be exercised in guarding against exposure to cold and damp for a long period after apparent recovery has taken place. When able to be moved, a change of air is above all things the best, especially from the city to the country.

---

#### STEAMING THE UTERUS IN SEPTIC CONDITIONS FOLLOWING ABORTION, ETC.

Some months ago we presented the substance of an article on this subject by Dr. Ludwig Pincus, of Dantzig. In the *Centralblatt für Gynäkologie* of February 20 that gentleman has a further communication on the matter. He reports the results in ten additional cases of sepsis following abortion. In five of them the fever disappeared speedily by crisis, in two lysis occurred, and in three there was no notable fever to begin with. The occurrence of lysis, he thinks, indicates infection of a moderate grade. In almost all the cases the odor ceased at once or became so slight as to be hardly noticeable. In one case the steaming had to be repeated on the third day, and then lysis set in. At the time of the appearance of the lochia, on the third or fourth day, he began the use of vaginal injections of sterilized physiological salt solution, and in one case he used injections of potassium permanganate.

The treatment he regards as still in the experimental stage, and he acknowledges that thus far he has employed it with the feeling that there was a certain amount of risk, especially of inoculating fresh wounds with infectious germs. But he adds that it seems to him a very plausible procedure for reducing the risk to the minimum, particularly in neglected cases, for it not only destroys the germs and covers fresh wounds with a protective coagulum, but induces energetic uterine contraction, whereby the traumatic surfaces are decidedly reduced in size, and involution, which generally means convalescence, is remarkably promoted. He thinks the treatment is especially suitable in cases of so-called habitual abortion, which so commonly depends on a diseased state of the endometrium, that may be overcome by two minutes' steaming at  $212^{\circ}$  F., followed for six or eight days with applications of tincture of iodine.

Dr. Pincus makes it a *conditio sine qua non* that the steaming shall be employed only when there is no complication affecting the adnexa, although incipient inflammatory phenomena—but without suppuration—with irritation of the peritoneum (quoting from Kahn) may be favorably affected by the steam. In the treatment of abortion he does not resort to active interference unless the indication of hemorrhage, fetor, or fever is present. Whatever remnants of the ovum there may be in the uterus he removes with the finger oftener than with the curette, and then irrigates the uterine cavity with an antiseptic solution, using Playfair's tube, and repeating the irrigation daily for several days if necessary. In addition he applies cold compresses or ice-bags to the abdomen, and always gives ergotin subcutaneously. He maintains that the steam treatment is a specific for septic abortion, and probably also for uncomplicated puerperal endometritis, but he closes with the qualifying remark, "*specifica non sunt, nisi in manu periti.*"—*New York Medical Journal*, March 20, 1897.

#### CHLOROFORM AND THE HEART.

In an editorial in the *British Medical Journal* of April 24, 1897, is discussed an important paper, which so completely supports the views expressed in the THERAPEUTIC GAZETTE in various issues that we venture to reprint it, although it is based entirely on a Progress article in this same issue from the *British Medical Journal* of April 17:

"In an address delivered before the Society of Anesthetists on February 18, which was published in the *British Medical Journal* of April 17, Mr. Leonard Hill brought forward additional evidence of the incorrectness of the doctrine, promulgated by the Hyderabad Chloroform Commission, that chloroform has no direct action on the heart. This new evidence is the outcome of his researches into the influence of the force of gravity on the circulation of the blood, which were communicated to the Royal Society in November, 1894, and published in detail in the *Journal of Physiology* in the following year. When an animal is turned from the horizontal to the feet-down position, the cannula in the artery being ingeniously placed in the axis of rotation, there is a fall of blood-pressure in the carotid, and a fall of intracranial pressure. The fall of blood-pressure is not great, and in a normal animal under morphine it soon rises to but a little short of the pressure recorded in the horizontal position. The mechanism of this recovery or compensation has been carefully investigated by Mr. Leonard Hill, and he has shown that it depends upon the integrity of the vaso-motor and respiratory systems, together with the efficiency of the heart. In the feet-down position the blood accumulates in the vessels of the abdominal viscera, and it is 'lifted' on to the heart by an increase of tonic constriction of the splanchnic vessels, aided by an increase of abdominal pressure brought about by contraction of the muscles of the abdominal wall. Previous section of the splanchnic nerves, or division of the dorsal spinal cord, by removing the tone of the splanchnic vessels, leads to a much greater fall, and does away with the power of compensation, although the animal endeavors to drive on the blood by powerful contractions of the expiratory abdominal muscles. When these are also divided the blood-pressure falls still lower. If the chest is opened the heart is seen to be bloodless and empty, but can be immediately filled by pressure on the abdomen. Increased activity of the vaso-motor center is the main factor in bringing about the recovery of pressure.

"It is interesting to note that in an 'upright' animal, such as the monkey, the compensating mechanism is very efficient and prompt, and in fact there is frequently over-compensation, so that the carotid blood-pressure is higher in the upright than in the horizontal position. The same is the case in man, and this has been clearly shown by Dr.

George Oliver with his ingenious instrument, the arteriometer. This instrument gives an indication of the pressure in an artery by measurement of its diameter, and shows that the diameter of the radial artery of a healthy man is greater in the sitting than in the recumbent position. In the upright position the heart beats faster, for it has more work to do in sending the same quantity of blood through the brain and through the abdominal viscera back to the heart again. The increased work of the heart is the third factor in bringing about compensation on change of position. As long as the heart is able to do this very small increased amount of work the pressure recovers; but if it is not able to do it, only an incomplete and poorly sustained compensation is brought about.

"Now, Mr. Leonard Hill finds that chloroform is a most powerful agent in doing away with the power of compensation. With moderate anesthetization the fall of blood-pressure on turning the animal into the feet-down position is very considerable, and that the blood largely accumulates in the splanchnic vessels is shown by the considerable recovery of pressure, though short of normal compensation, brought about by compression of the abdomen. This compression drives blood on to the heart, and the heart forces some of it on into the arterial system. Very different is the result when the anesthetic is pushed: a very great fall of pressure is produced, and compression of the abdomen, or even turning the animal feet up, leads to no adequate rise of pressure. The feet-up position does not restore the pressure to as high a level as that which was maintained in the feet-down position before the chloroform was pushed. It is no use squeezing blood on to the heart, for it is incapable of dealing with it. A heart under the influence of chloroform is not able to do the small additional work required to maintain anything like the same pressure when the animal is turned from the horizontal to the vertical position.

"The experiments show the essential difference between a low pressure produced by vaso-motor paralysis and one produced by chloroform, and leave no doubt whatever that the dangerous fall produced by the drug is due to direct action of the heart. So that from an entirely different standpoint the work of MacWilliam, Ringer, and others, and the results obtained by the elaborate cross-circulation method of Gaskell and Shore, are completely confirmed. Mr. Leonard Hill

points out that the tracings of the Hyderabad Commission also show that failure of the circulation is really the cause of death; for the respiration stops, not because the center is paralyzed, but because the blood-pressure has fallen to a certain amount, and it recommences when this is by any means raised to that amount again, although the center is thereby supplied with as much chloroform as before. In fact the tracings of the Commission, as Dr. Gaskell and Dr. Shore have pointed out, are, so far as they go, as good as any others; they are infallible records made by the animals themselves, and when read by competent physiologists tell the same tale as all others do.

"Mr. Leonard Hill has not omitted to point out the practical bearing of his experiments on the treatment of that commonest cause of death from chloroform—syncope in an early stage. In one year, out of forty-one deaths from chloroform syncope, thirty-nine occurred in the primary stage before the patient had been touched by the knife. The sudden application of concentrated chloroform vapor causes struggling and holding of the breath, the glottis is closed, and intrathoracic pressure is raised; the lungs are thereby compressed and largely emptied of blood: this leads to engorgement of the right heart and congestion of the venous system, until at last two or three very deep respirations are taken, and there is a sudden rush to the left heart of a mass of blood surcharged with chloroform. The heart, already dilated, is then paralyzed. Holding strong chloroform vapor to the nostrils of a struggling patient is to court disaster.

"When syncope has occurred the chief thing to do is to relieve the heart of blood and not to drive blood to it, as is so often done by inversion or flagellation. Artificial respiration is to be applied in the horizontal position by forcibly compressing the chest rhythmically, with the object of bringing pressure to bear on the heart. If this is not immediately successful the same maneuver must be carried out in the vertical feet-down position, and under no circumstances must the abdomen be compressed or the patient inverted. If only a little blood can be forced through the heart and the pressure on the right side be sufficiently relieved spontaneous contraction will soon occur, and as the blood-pressure rises respiration will begin again. Mr. Leonard Hill's experiments afford additional proof of the difference in action of ether and chloroform. With ether the fall

of pressure is much more gradual, and when the animal is placed in the feet-down position the drop of pressure is comparatively small; but even when the ether is pushed and a low pressure produced it can be at once raised by compression of the abdomen or by the resumption of the horizontal position. The heart is comparatively little affected, and, as the blood is brought to it, it can pass it on, but the chloroform heart cannot. As to the physiological action of chloroform, and the comparative safety of ether, recent experiments on animals are, we are glad to see, in complete accord with clinical experience."

#### *THE CAUSATION OF CHLOROFORM SYNCOPE.*

In the *British Medical Journal* of April 17, 1897, LEONARD HILL of London concludes a valuable paper supporting that of Hare in the *GAZETTE* for February, 1897. He says from the previous experimental discussions in this paper it is conclusively proved that chloroform may paralyze the heart, the vaso-motor mechanism, and the respiratory center. If it happened that we simply had to deal with failure of the respiration this would be no matter of grave danger to the patient. Artificial respiration will remove the danger. If simple vaso-motor paralysis occur concomitantly with failure of respiration, as is always the case, artificial respiration combined with slight elevation of the abdomen to a level above that of the heart would immediately restore the patient to safety. It is when the clinician has to deal with the paralytic dilatation of the heart that the gravest danger has to be faced. As it is impossible to diagnose whether this condition may exist or not, every case of chloroform syncope should be treated as if it did exist. Recovery can be brought about, and, so far as the writer's own experience goes, practically in almost all cases, by following this simple procedure: At the moment syncope occurs the patient must be placed in the horizontal position, and artificial respiration applied. The chest must be rhythmically compressed by placing the hands on each side of the thorax, so that the heart may share in the compression, and the circulation through that organ may by artificial means be maintained to a certain extent. If this is not quickly successful in restoring the pulse and natural breathing, the patient should be turned into the vertical feet-down position. By this means the dilated right

heart will be emptied into the abdominal veins. Whilst this is taking place, artificial respiration must be maintained. The writer states he has frequently seen the paralyzed heart start beating again on thus emptying it of the blood. After a few seconds the patient should be returned to the horizontal position, and the right heart will thus be refilled with a fresh supply of venous blood. By means of the artificial respiration this blood is driven on through the lungs to the left heart, and thence into the coronary arteries. If this maneuver does not prove successful at the first attempt, it must be repeated. Since he has adopted this method he has scarcely failed to recover a single case of chloroform syncope. The success enormously depends on the swiftness with which the condition of syncope is recognized. Nelaton's inversion, or the feet-up position, is only a safe measure in cases of syncope arising from vaso-motor paralysis. Either inversion or compression of the abdomen are fatal mistakes in cases of cardiac failure. A poisoned heart is with greatest ease thrown into paralytic dilatation by compressing the abdomen, as shown by a number of experiments.

By rhythmically and artificially compressing the thorax or the heart he has found it possible to maintain an arterial tension of twenty to thirty millimeters Hg. This causes the coronary arteries to be flushed with fresh blood, and the heart to be excited to spontaneous contraction. After the circulation has thus been renewed, the respiration frequently remains in abeyance because the arterial tension is too low to excite the center to activity. In this condition the best plan is to cease artificial respiration, and carefully observe the pulse. The arterial tension, on account of the asphyxia, will rise, and when it has reached a certain level spontaneous respiration will start once more. If by any chance the pulse should show signs of again flagging artificial respiration must be immediately resumed for another period.

As to the danger of administering chloroform the author entirely agrees with the Hyderabad Commission that the inhaler should only be applied when the respiration is quiet, and should be removed entirely if the patient shows any sign of struggling. If this precaution be always taken deaths from chloroform would become far more rare; nevertheless, it must always be looked upon by the inexperienced as a most dangerous drug, and one the use of which should be avoided whenever ether can be appropriately substituted.

Pure chloroform, he has found, kills in exactly the same way as impure chloroform. The A. C. E. mixture, on the other hand, is safer than pure chloroform simply because the latter drug is diluted, and therefore is not given in a concentrated form. Chloroform is the predominant partner in the mixture, and when A. C. E. is pushed the animal dies with all the symptoms of chloroform syncope.

Towards the close of his paper Hill says chloroform produces a primary failure of the circulating mechanism and a secondary failure of the respiratory center. The respiratory center fails to act not only because it is damaged by the drug, but because of the anemia of the spinal bulb produced by the fall of arterial tension. This is proved by the fact that the action of the respiratory center can be renewed by raising the arterial tension. The depth of anesthesia depends, as does the paralysis of the respiratory center, on the primary fall of the arterial tension.

Chloroform, more than any other known agent, rapidly abolishes the vascular mechanisms which compensate for the hydrostatic effect of gravity.

Chloroform abolishes these mechanisms by paralyzing the splanchnic vaso-motor tone, and by weakening the action of the respiratory pump. When these mechanisms are totally abolished the circulation is impossible if the subject be in the feet-down position.

Chloroform also produces paralytic dilatation of the heart. It acts directly like amyl nitrite on the musculature of the whole vascular system.

There are two forms of chloroform syncope: (a) During primary anesthetization the patient struggles, holds his breath, raises the intrathoracic pressure, congests his venous system, lowers his arterial tension, and finally takes deep inspirations and surcharges his lungs with chloroform. In the first stage the left heart becomes impoverished; in the second stage it is suddenly filled with blood. This is drawn from the lungs, and is full of chloroform. The chloroform passes into the coronary arteries, and the heart is thrown into paralytic dilatation. Respiration and the pulse either cease simultaneously or the pulse before respiration. (b) During prolonged anesthetization this arises from gradually giving chloroform to too great an extent. The arterial pressure falls lower and lower, and secondarily the respiration ceases because of the anemia of the spinal bulb. The heart is not in this case paralyzed by chloroform, because the drug is taken in gradually

by the shallow respirations, and distributed slowly by the feeble circulation.

Artificial respiration and the assumption of the horizontal position, if applied in time, will always resuscitate a patient from the second form of syncope.

Artificial respiration, established with the patient in the horizontal posture, is also the treatment indicated in the first form of syncope; the heart should be rhythmically compressed by squeezing the thorax. If this does not quickly renew the pulse, the patient should be put into the vertical feet-down posture. The dilated right heart is thereby completely and easily emptied of blood. Artificial respiration is maintained during this maneuver, and the patient is brought once more into the horizontal posture. By rhythmic compression of the chest an efficient circulation is maintained through the coronary arteries; by first emptying and then filling the heart a fresh supply of blood is brought into that organ. If this does not prove successful on the first trial it can be repeated.

Inversion—that is, placing the subject in the feet-up position—or compression of the abdomen will increase the paralytic dilatation of the heart. In this kind of syncope both these forms of treatment are worse than useless.

In the condition of shock or emotional fear the compensatory mechanism for the effect of gravity is almost abolished, and chloroform may easily be the last straw to completely paralyze the circulation.

Vagus inhibition of the heart is of no importance as an agent in the production of chloroform syncope.

Ether is in every respect a far safer anesthetic than chloroform. According to Ringer's experiments on the heart, ether is fifty times less dangerous than chloroform.

With the practical conclusion of the Hyderabad Commission that the chloroform inhaler should be removed during the struggling of the patient or when the respiration is of irregular depth the writer is in absolute agreement, but he considers their interpretation of their own experiments and tracings concerning the origin of chloroform syncope to be mistaken.

Not only the work of all physiologists, but also the tracings of the Commission, when rightly interpreted, prove that paralysis of the circulatory mechanism, and not of the respiratory center, is to be dreaded by the anesthetist.

## ON SENILE ENDOMETRITIS.

HERMANN in a new English journal called *Treatment* tells us that when consulted by an old woman about a copious purulent vaginal discharge the vagina should be first treated. Swab the vagina out with strong (!) carbolic acid, and prescribe frequent astringent injections, such as zinc chloride, five to ten grains to the pint. Begin with the weaker and increase the strength if necessary. Repeat the application of strong carbolic acid two or three times, if necessary, with weekly intervals. Take care that none goes on the vulva. If discharge comes from the uterus, there may be so little of it as not to trouble the patient when the vaginal discharge has been stopped. If treatment of the vagina does not abolish the discharge the cervix should be dilated with laminaria tents (!), and the interior of the uterus explored. If growths are felt they should be scraped away and examined with the microscope. If there are no outgrowths the endometrium should be scraped with a blunt curette, any bits detached reserved for the microscope, and then the interior of the uterus swabbed with strong carbolic acid. This will almost always remove the symptoms for a time. If after a short interval they return, and become as bad as before, the best treatment is to remove the uterus.

Matthews Duncan advised the injection of mild astringents into the uterine cavity through a hollow sound. His great authority makes the writer think this worth trying in the case of a patient averse to operation. Duncan says it often fails; and the writer expects little from it.

## LAPAROTOMY IN TUBERCULOUS PERITONITIS.

VON MARCHTHURN (*Wien. Klin. Woch.*, March 4, 1897) records nineteen further cases of this affection operated on by Chrobak. No patient died directly from the operation, but one succumbed the day after from inanition. Twelve patients recovered entirely from the peritonitis, but two of them died five months and two years respectively after the operation, of pre-existing pulmonary disease. In three cases a second laparotomy was necessary three to seven months after the operation; two of the patients recovered completely; the third died of pulmonary tuberculosis five months later without abdominal recurrence. Two patients had been tapped before the operation; one of these

was cured, the other could not be traced. Eleven of the cases were complicated with lung trouble: of these three died, two from the pulmonary affection, the abdominal mischief having healed, the third from exhaustion. All the eight patients with sound lungs recovered. The author is disinclined to follow Spaeth in forbidding operation in patients with lung disease. In six cases there was tuberculosis of the generative organs; in four both sets of appendages were affected, but too tightly bound down by adhesions to be removed. In three of these the tumors disappeared after the operation; the fourth patient left the hospital relieved, but was then lost sight of. Of the other two patients, one, who died the day after operation, had a tuberculous abscess of the left ovary; the other, a tubo-ovarian cyst, which could not be removed, and which eighteen months later had given rise to no further trouble. Three cases had high temperature before operation; these did perfectly well, and in only one of the others did the thermometer register 100° F. after laparotomy. The diagnosis was invariably verified microscopically. The after-history was unfortunately deficient in six cases. Altogether out of thirty-eight cases treated by Chrobak in the years 1896-97 by simple laparotomy, twenty-one (fifty-five per cent.) were completely cured. The most rational explanations of these cures appear to be stimulation of the peritoneum and the removal of fluid from the abdomen; the former is the more generally applicable, as dry tuberculous peritonitis is equally adapted to the treatment. The author concludes by giving Chrobak's opinion that in tuberculous peritonitis medical treatment is useless, and tapping at best but of temporary service; incision, and if necessary evacuation of the abdominal contents, afford by far the best chances of recovery.—*British Medical Journal*, April 17, 1897.

## PRURITUS.

DIRNER (*Centralblatt f. Gynak.*, No. 5, 1897) introduced, by reading a paper on the operative treatment of pruritus, an important discussion on that disease at a recent meeting of the Royal Hungarian Medical Association. He admitted that the diabetic variety was curable; so was that form of pruritus due to microbes in vaginal or cervical secretion. The intractable cases were clinically and pathologically primary. They represented subacute inflammation of the vulvar

integument and fibrosis of the Pacinian corpuscles and other delicate structures. Dissecting off the skin involved in this morbid process, "vulvitis pruriginosa," alone effects a cure. He read notes of two cases, one particularly obstinate, where the patient was aged 65. He dissected off all the vulvar integument from the mons veneris to the navicular fossa, taking away the clitoris. The wound was sutured with silver wire, and covered with iodoform collodion. It healed by first intention. After healing there was no tension, though so much skin had been removed. Tauffer found that pruritus from germs, secondary to leucorrhea and endometritis, is very hard to treat. Besides treatment of the existing cause, free application of sublimate lotion is needed. Diabetic pruritus is certainly difficult to cure. Kezmarszky agreed with Dirner as to a primary prurigo due to degenerative changes in the skin, and needing operation. He found, contrary to Tauffer, that the secondary forms, pruritus from diabetes and from germs in discharges, yield readily to symptomatic treatment.—*British Medical Journal*, March 27, 1897.

*CATHETERISM OF THE URETER IN THE  
MALE WITH THE HELP OF THE  
URETER CYSTOSCOPE—A RE-  
PORT OF SEVEN CASES.*

In the *Medical Record* for May 1, 1897, WILLY MEYER publishes an article in which he says: There is no longer such a thing as testing the efficiency of this procedure. Let it be generally understood that to-day the ureters of the male can be catheterized and the kidneys drained without a previous cutting operation. But the method has its limitations, as cystoscopy has when carried out with Nitze's instrument. The method will and must be a failure whenever the three cardinal conditions which permit cystoscopy cannot be fulfilled, viz.:

1. If the caliber of the urethra is not sufficiently large to allow the passing of the instrument.
2. If the bladder has not a capacity of at least four or five ounces.
3. If the fluid within the bladder cannot be made and kept transparent.

Now and then these cardinal conditions are fulfilled, and yet the method proves unsuccessful owing to the fact that the mouths of the ureters cannot be found, or that they cannot be approached, or that they are too small to allow the entrance of even the finest

of catheters. Sometimes the catheter has well entered the ureter, but it soon becomes plugged by descending blood or pus.

With reference to the work itself, the author can repeat to-day what he said a year ago: He considers the manipulation here in question an easy one, in the male as in the female. He has not changed his views since then. To approach the ureteral mouth and engage the tip of the tiny catheter in the same is not a bit more difficult in the male than it is in the female.

Of course, in order to be successful a perfect familiarity with cystoscopic work is required. He who thinks that for catheterism of the ureters in the male it is merely necessary to buy Casper's or Nitze's instrument and then proceed, is very much mistaken, and will no doubt be disappointed in his attempts, surely in his first ones. He had practised cystoscopy with Nitze's instrument in the male and female for fully eight years before he catheterized the ureters in the male for the first time. The reason for this was not that such a long preparation is needed, but simply because a useful instrument was not to be had sooner. Such was not for sale before 1895. But during these eight years he had learned in many hundreds of cases how to find the ureteral openings, even under adverse and difficult conditions. He had learned how to approach them even in such cases. For half hours at a time and longer did he in a great number of instances uninterruptedly watch the ureteral jets for the sake of determining the transparency or turbidity of the descending urine. He had carefully timed the outflow with a view to finding the working coefficient of the respective kidney. Often did he do this for so long a time that he was forced to stop because of the running of his eyes due to the severe strain. If the cystoscopist knows how, the author might say, to "handle" the ureteral openings he will surely enjoy this kind of work, as the author has done from the very beginning.

But he who does this sort of work in the male should always have made up his mind to proceed with patience and perseverance; he must not be in a hurry. His patients come on special appointment. It has taken him at times fully two hours before he got through, and then, in one instance, he had to be satisfied with the collection of 4.5 cubic centimeters from the one kidney; in another case the catheter did not give exit to any fluid whatever on the one side. But

the reason for this annoyance was not the difficulty of the procedure, but some mechanical obstruction of the catheter's eye or lumen. Plugs of descending pus, the smallest amount of coagulated blood, with some pushed-off epithelial cells of the ureter, may easily obstruct the eye of the tiny catheter. If repeated aspiration with a powerful syringe attached to the outer funnel-shaped end of the ureter catheter does not soon make the urine flow through the catheter, one ought to pull back the catheter's tip into the bladder, then wash out the canal with sterilized boric-acid solution, the eye of the ureter catheter being within the vesical fluid, and then reintroduce the instrument. As mentioned above, he did this maneuver in the case of a lady three times. At the fourth reintroduction urine at last began and continued to flow through the catheter.

He further wishes to mention the necessity of good assistance when catheterizing the ureters. He believes it is impossible to do good ureteral work in the male without a trained hand at one's side. He has so far always had and needed the help of his office nurse. She thoroughly knows what he wants, how to fix the cystoscope and the catheter when he pulled out the mandrel, how to steady the instrument when the catheter is *in situ*, etc. All these points to be observed when carrying out the work may at first seem cumbersome and superfluous, yet he deems them absolutely essential for successful ureteral work in the male.

In summing up these remarks he would say that repeated disappointment in the early time of ureteral work in the male should not discourage the cystoscopist. On the contrary, it should stimulate him to further trials. The reason for his failure should be sought rather in lack of experience in intravesical cystoscopic work, and also perhaps in lack of proper assistance, than in the imaginary defect of the instruments used for this purpose. Both of the ureter cystoscopes now in our hands are useful and do not need special improvement.

In order to be successful in using Casper's instrument, one will do well, he believes, to follow the rules he has laid down in his former article, repeatedly referred to—rules which he has found practical by personal experience. They are, briefly repeated and revised, and extended after his additional experience, as follows:

1. Wash and cocaineize the bladder according to well known rules.

2. Fill the bladder with from five to seven ounces of clear fluid.

3. Introduce the instrument. For this purpose the ureter catheter should be pushed down to the internal opening of the canal of the cystoscope; the lid of the latter should be pulled out about one-third inch.

4. As soon as the beak has entered the bladder the catheter should be gently pushed forward into the vesical cavity about one-half to three-quarters of an inch, and then the lid should at once be pushed back into place, *i.e.*, it should be fully closed.

5. After the interior of the bladder has been inspected and the ureteral openings have come into view, approach one of them.

6. Let the ureteral opening appear at the very end of the cystoscopic picture, farthest away from the middle of the bladder; but keep it under your direct inspection, with the prism as near to it as possible.

7. Push the catheter gently forward; if the beak's direction is a proper one, *i.e.*, if it is parallel with that of the lower end of the ureter, he is sure the ureteral catheter will almost invariably easily enter the mouth, when conducted by a trained hand.

8. Allow the catheter to proceed not more than one or two inches into the ureter, and withdraw the wire mandrel. Then, as a rule, urine will begin to flow drop by drop at intervals or continuously.

By faithfully adhering to these rules in the author's work, he has invariably been successful. Of course, the number of patients thus treated is not yet very great. But, so far, he can repeat conscientiously that whenever, in male or female, he has been able to see and approach the ureteral opening, he has also succeeded in introducing the catheter into the same. He has specially added the words "so far" because he has no doubt that he may probably encounter cases in the future in which his attempts will not be crowned with success, although the ureteral openings can be well seen and approached. But up to date there has been only one among all his cases, male and female combined—a patient of Dr. F. Cushier and Dr. Robert F. Weir, of this city—in which he has failed in his repeated attempts, although he saw the opening very distinctly before him. However, in this patient he afterward also failed with Kelly's method in repeated sittings. There was no catheter or probe small enough, metal or flexible, to enter the mouth. The reason for this was partially, as had been primarily well ascertained with the cysto-

scope, that the ureter emerged, not as is usually the case, at the innermost end of the ureteral intravesical fold—*i.e.*, nearest the trigonum—but about one centimeter away from it upwardly. The consequence was that the ureter catheter, in order to pass on, would have had to turn in a sharp angle right after its entrance into the ureteral mouth. This seemed not feasible. Besides, the mouth of the ureter was constricted, evidently congenitally. Such strictures we have to put on a basis with the congenital narrowness of the external meatus, so often found in the male. By chance he nevertheless succeeded in determining the question at issue, viz.: Is the opposite kidney healthy? He adds this here because the case really was a perplexing one. There had been an intermittent renal pyuria for the last two years. The right kidney was large, easily palpable, slightly painful to the touch. At the third sitting it struck him at once that when washing out the bladder the water returned clear from the beginning. He concluded that on this day the ureter of the diseased side was most probably temporarily obstructed. Cocainization of the bladder was somewhat prolonged on account of making preparations for the following work. It may have taken in all about six or seven minutes. During this time the patient, who had taken a great deal of fluid before going to the author's office, discharged five ounces (!) of urine into the bladder. Instead of drawing off 50 cubic centimeters of the cocaine solution and perhaps 10–20 cubic centimeters of meanwhile admixed urine, he measured 200 cubic centimeters (50 cubic centimeters of a two-per-cent. solution of cocaine had been injected by him). On viewing the bladder after Kelly's method he saw that the ureter of the presumably diseased side, which emptied within the center of an irregular ulceration, did not discharge a drop of fluid. Examination of the 200 cubic centimeters of mixed cocaine solution and urine proved the latter to be perfectly normal. In other words, there was a well-working, healthy opposite kidney. Dr. Weir successfully removed the diseased kidney. The operation, as well as the specimen thus obtained, proved to be of unusual interest.

Whether we should advise patients to take a large amount of fluid before examination is still a mooted question. In the male he believes it is a wise plan. As explained in his former article, in the male we must drain one kidney after the other—if possible,

of course, always in the same sitting. That is to say, we cannot generally leave the catheter first introduced into one ureter in place; liberate it; catheterize the opposite side, leaving the catheter there also *in situ*; remove the cystoscope. There will be few urethræ found in the male of sufficiently wide caliber to allow properly moving the cystoscope with the catheter at its side within the urethra. It may often be possible under general narcosis. The latter, however, it seems to the author, should for various reasons be avoided as much as possible in this procedure. We drain the kidneys separately for renal disease, and ether as well as chloroform is detrimental to the renal tissue. So far, he never used or needed general anesthesia for his ureteral work. This, as mentioned above, has been office work throughout.

In the male we are, therefore, limited in time. The sooner the patient gets through, the better. The more fluid he has taken before the examination, the more rapidly his kidneys will work. Of course, due weight must be given this point in drawing conclusions from the urinary analysis. However, as both kidneys have been subjected to greater work at the same time, mistakes can be avoided by a competent analyst.

In the female the case is different. Both kidneys may be drained for hours, provided we do the work at the patient's home or at the hospital. The urine from each can be separately collected in proper bottles put into the bed. We certainly can state the fact: Urinary analysis will be more satisfactory without diluting the renal secretion too much by previously ingested fluids.

With reference to finding out the amount of work done by each kidney within a given time, he formerly counted the drops that were discharged through the ureter in a certain number of seconds, and also counted the intervals between the different discharges. He has discarded this method since he has distinctly seen jets of urine at the ureteral opening enter the bladder with the ureter catheter *in situ*. The urine evidently often drains alongside the catheter besides passing through its lumen. The catheters which accompany Nitze's ureter cystoscope are of more use in this respect than those of Casper's instrument. The former have an end hole behind a scoop-shaped lengthening of the material of which the catheter is made, the whole thus forming a sort of bougie. The latter carry the eye at the side. Neverthe-

less he believes that timing the number of drops discharged through the ureteral catheter is an unreliable observation.

His whole work with a cystoscope according to Nitze's principles has, so far, been done with Casper's instrument—this for the simple reason that the first specimen of Nitze's reached him in a damaged condition. Before it was exchanged by the factory, more than half a year elapsed. He will certainly try it the first opportunity that offers.

Whether in the female one should make use of a cystoscope constructed on the Nitze plan, or of Kelly's instruments, is really a matter of taste. The manipulation with the imported ureter cystoscope certainly is a very gentle one; it is also very comfortable for the patient. She rests her back in the position used by us for bimanual vagino-abdominal palpation.

A trained cystoscopist should, in the author's opinion, be master of all methods "that have proved useful and can be made use of for this purpose." In many instances he may, even in the female, succeed with the one method or instrument when the other failed for certain reasons.

In the male we have no choice. As explained at length above, Kelly's method for catheterism of the ureters is here a technical impossibility. We need instruments which carry the electric light into the bladder, and enable us at the same time to inspect and catheterize the ureteral openings by looking through a telescope and guiding the catheters through a separate channel.

With regard to the indication for catheterism of the ureters, it is in his opinion our duty to try to separately collect and analyze the secretion of each kidney "in the male as well as in the female" in all so-called obscure urinary diseases, provided the analysis of the bladder urine points to a renal lesion. It becomes our solemn duty to establish the presence, the health or disease, if possible also the working power, of the opposite kidney if nephrectomy has to be done.

If physicians will appreciate the importance of this now feasible examination, and make it a point to have cystoscopy and catheterism of the ureters in the male as well as in the female added to the other means at their disposal for arriving at a definite diagnosis, then the so-called obscure urinary diseases will at last become a thing of the past in the male also, and our diagnosis in the majority of such cases will from mere guesswork be put on a strictly scientific basis.

#### RESECTION AND EXTIRPATION OF THE LARYNX FOR MALIGNANT TUMORS.

Many lives could be saved if the diagnosis of malignant tumors could be made earlier. A writer in the *Beitrag z. Klin. Chir.* urges physicians and students to master more thoroughly and universally the technique of laryngoscopy, so that malignant neoplasms can be discovered more frequently and removed in their incipient stages. Mikulicz has found that a normal function can be retained if two-thirds of the larynx can be saved. Important in this respect is the secondary suture to decrease the size of the wound, and the prevention of the formation of epidermis from the edges in. In thirteen cases operated, four have remained in good health since, one and one-half to eight and one-half years. One succumbed shortly after the operation; another died later of phthisis. In five cases the tumor grew again in three to ten months, with a fatal result in four. In six cases superior tracheotomy was performed, and inferior in the rest. Hemostasis was secured by ligatures and lateral compression; only once was the thermo-cautery necessary. He considers frequent changing of the bandages very important. Food was taken by the sound through the wound or lower nasal passages. He has never applied an artificial larynx.—*Centralblatt für Chir.*, March 13, 1897.

#### FAVORABLE EFFECT OF LAPAROTOMY ON TUBERCULOUS PERITONITIS.

GATTI has produced experimentally tuberculous peritonitis and then cured it with a laparotomy; gradually the tuberculous cells and the bacilli disappear, the products of degeneration are absorbed, and a process of reorganization ensues, in the course of which the peritoneum becomes normal not only to the eye, but to histologic and bacteriologic tests also. The process requires six to eight months, and the laparotomy, to succeed, must be performed at the proper moment, neither too soon nor too late, the tubercle fully developed and before the caseous degeneration has begun. As it is difficult in the clinic to determine the exact moment when the operation is needed, Gatti recommends a second laparotomy if the first proved ineffectual, and it was noticed that caseous degeneration had not begun. Burci ascribes the effect of the laparotomy to the combination of trauma, change of temperature, admission of light and air, etc.—*Gaz. d. Osp. e. d. Clin.*, No. 13, 1897.

*THE TREATMENT OF HYPERTROPHIC RHINITIS BY RESORCIN.*

GONZALES CAMPO (*Annales des Maladies de L'Oreille du Larynx*, No. 5, 1897) holds that hypertrophic rhinitis depends either upon a myxedematous degeneration of the mucous membrane or hyperplasia of the submucous connective tissue, consecutive to a chronic coryza. It often accompanies and usually precedes pulmonary phthisis. Bougies, massage, electrolysis, chemical cauterization and galvano-cautery have all failed to cure the trouble.

The author has succeeded with baths of one-per-cent. solution of resorcin. He has treated more than 125 cases. All were cured in about two months, the treatments being repeated every two or three days.

The first effect is one of irritation, followed in an hour or two by retraction of the hypertrophic tissue. Treatment is not applicable to neuropaths.

Castaneda in considering the anti-diphtheritic treatment in ozena states that one statistical table comprises 32, another 24, and that in this entire list but two undoubted cures have been obtained. He notes amelioration but not a cure in one of Compaired's cases. When cases of ozena are due to tuberculosis or hereditary syphilis, diagnosis may be determined by the use of tuberculin or mercury.

*THE NEW TREATMENT OF OZENA.*

COMPAIRED (*Annales des Maladies de L'Oreille du Larynx*, etc., No. 5, 1897) reports seven cases of ozena treated by hypodermic injections of antidiphtheritic serum. In two instances roseola developed, in one an abscess at the seat of injection. In some instances there was fever, loss of appetite, nausea and general debility. In one instance treatment had to be suspended on account of the frequency and intensity of the nausea. This case was scrofulous, semi-rachitic and profoundly anemic before treatment. The number of injections employed varied from four to twenty-seven. The quantity at each injection was from four to twenty centimeters. The first symptom noted was disappearance of odor. This was followed by edema of the mucous membrane, augmentation and fluidification of secretion.

During the treatment the author used only nasal irrigations of warm sterile salt water, followed by a nasal spray. The conclusions he announces are as follows: This treatment has given more pronounced and satis-

factory results than any other yet proposed for ozena. The results are characterized by the disappearance of the odor after the second or third injection of five or six cubic centimeters, and by diminution of the clots and increase of the nasal fluid. The mucous membrane changes in color, becomes redder, more humid, sometimes slightly hyperemic. The crusts are less heavy, dry and extended, and become softer as the treatment progresses. Doses of ten cubic centimeters are not unattended with risk. The dosage should be increased very gradually.

*THE CURABILITY OF DEAF-MUTISM.*

VERDOS (*Annales des Maladies de L'Oreille du Larynx*, No. 5, 1897) would ascribe deaf-mutism to the otopathy acquired in infancy consecutive to acute rhinitis. From neglect there follows atrophy of the acoustic nerves. Verdos believes that these cases would be curable if the nerves could be stimulated to proper development by vibrations carried through the cranial vault. He states he has cured a dozen deaf-mutes, but sometimes it has required several years. The naso-pharynx received particular attention, the drum was mobilized by means of Politzer's inflator and by the apparatus of Delstanche, and the patients received oral instructions. He would earnestly call the attention of doctors to the cases of acute rhinitis in children, which should be energetically treated.

*THE REMOVAL OF HIGH-LYING CANCER OF THE RECTUM BY KRASKE'S METHOD.*

SWINFORD EDWARDS (*British Medical Journal*, May 15, 1897) writing upon this subject states that according to the height to which the growth extends so must we plan our operation. For anal carcinoma the old perineal operation suffices. Where the disease extends to the level of the sacro-coccygeal articulation behind, probably a coccygeal excision will suffice, or if more room is required the sacro-sciatic ligaments may be divided. For cases extending up still further, even as far as the pelvic brim, the removal of the lower portion of the sacrum, or Kraske's operation, must be undertaken.

Sacro-coccygeal excision not only lets plenty of daylight into the bottom of the wound, and greatly facilitates accurate suture of the perineum, but enables us, in fit cases, to restore the continuity of the gut after removal of the diseased portion.

That which really militates against the success of any rectal excision is the fact of lymphatic infection, or of the extension of the disease beyond the rectal walls, when the growth, instead of being movable with the rectum on its bed of adipose and areolar tissue, is bound down and fixed to the neighboring parts. Where these factors are present attempts at extirpation can only end in disaster. Another bar to operative interference is, according to Mr. Cheyne, a rapidly-growing carcinoma.

As to the advisability of a preliminary colotomy, it has much to recommend it as a preliminary to perineal excision. When we adopt the sacral route, however, it is quite unnecessary on the following grounds:

1. Any wound of the serous membrane can be seen and accurately closed, thus avoiding fouling of the peritoneum.

2. The loss of two or three weeks a previous colotomy entails may make all the difference between success and failure after excision.

3. It is not so likely to be followed by stricture as after the perineal operation, and therefore no subsequent colotomy is necessary; were it otherwise the writer would be inclined to regard it as an argument in favor of a previous one.

4. A colotomy may seriously interfere with or altogether prevent a rectorrhaphy by making it difficult or impossible to bring down the upper rectum by reason of the adhesions between the sigmoid colon and abdominal wall.

If not absolutely necessary, it is hard lines to saddle a patient with an abdominal artificial anus and to subject him to the risk—small as it is—of this extra operation. It might be said: "What does it matter where the artificial anus is placed? If a colotomy is performed the patient will be saved an anus in the sacral region!"

This, however, does not necessarily follow, as the end and aim of Kraske's operation is to restore the continuity of the bowel with use of the normal anus. Even where this cannot be carried out, patients seem to prefer the artificial anus to be placed somewhere between the folds of the buttocks, in the neighborhood of the original outlet. It must also be borne in mind that a previous colotomy is not an unfailing safeguard against peritonitis following injury to the serous membrane during the course of an excision; one of the patients treated by the writer succumbed on the ninth day after an excision,

although he had previously been subjected to colotomy.

It is important, in preparing a patient for the operation, to get the general health into as good a state as possible, and to clean out the bowels for some days before with aperients and enemata. As a first step in the operation he has made it a practise to wash out the rectum thoroughly with some antiseptic—sublimate solution, 1 in 2000, for choice.

With regard to posture, Littlewood's modification of Godlee's position has much to recommend it. He places the patient in the position used for dissecting the buttocks, raising pelvis on a block, and having both knees flexed and resting or kneeling on a chair.

After a longitudinal central incision about six inches in length through the soft parts down to the bone, it may be found that plenty of room is obtained by simply removing the coccyx. In one case, although the upper limit of the growth was on a level with the middle of the sacrum, removal of the coccyx gave ample room. If more is necessary, division of the sacro-sciatic ligaments on the left side may suffice. Whether more of the bone can safely be removed is a question, though Volkmann and Rose appear to have divided the sacrum transversely as high as the second foramen. For the purpose of effecting the division, some use a saw, but a chisel is much easier to work with, and more expeditious. To avoid wounding the soft parts under the bone, it is well to separate them with a periosteal elevator from the anterior surface of both sacrum and coccyx.

If any considerable bleeding takes place during the operation it is here that we may expect it, owing to wound of the middle sacral vessels. After their division they may retract and be difficult to seize, being concealed by the sacrum or what remains of it. Here it is that a good assistant is very necessary.

The bowel has now to be separated, in doing which it is as well after division of the levatores ani to keep to that plane of rectovesical fascia which surrounds the gut, and not to attempt to dissect the bowel out of its bed of perirectal fat; by thus doing much bleeding is avoided and time saved. Separation of the posterior and lateral walls having been effected chiefly with the aid of the finger, it remains to deal with the anterior. The author prefers to clamp the gut well above the growth and to cut it through, in doing which the peritoneum is generally

opened, when a sponge or gauze plug may be inserted temporarily and the dissection proceeded with from above downwards.

The writer gives a table of cases which show that he has several times in coccygeal excision avoided wounding the peritoneum; but he is not at all sure that one does not lose more than one gains by so doing—that is, if a junction of bowel is contemplated—for unless the serous cavity is freely opened it is often impossible to bring down the proximal end.

The question of deliberately and freely incising the peritoneum and subperitoneal tissue with a view to rectorrhaphy seems well worthy of consideration. Where one can avoid opening the peritoneum one should do so, even if it entails abandoning the rectorrhaphy; but where the peritoneum is wounded and the gut cannot be brought down without a freer division, such a course is justifiable in view of the end to be obtained.

The affected portion of the rectum having been removed, and any wound of the peritoneum carefully closed with a continuous suture, one is now able to determine the feasibility of intestinal anastomosis. If there is a sufficient length of the lower end saved, and too much tension is not caused by approximating the parts, it certainly should be attempted, for if not successful in the entire circumference a great deal is gained by union of the anterior part. As to the best means of effecting this, there is not much to choose between a bone bobbin and a direct suture. He has tried Murphy's button, but does not think that it is suitable to this part of the intestinal canal, on account of the absence of a peritoneal coat to the lower portion, so that there can be no union of serous surfaces. Maunsell's method is of course out of the question. In cases where we can be tolerably certain of performing a satisfactory circular rectorrhaphy it would be well to leave the coccyx and segment of sacrum attached by one or other border; in other words, to form a bone flap, as in the method of Roux, so that after the intestinal suture the parts may be replaced before finally suturing the skin. If the position of the growth necessitates the removal of the anus, it is of course useless to attempt to close the wound, excepting in its upper part over the exposed sacrum. A few sutures should fix the end of the gut to the skin margin below the sacrum, or if thought better a ligature may be passed round the bowel to occlude it, fastened to the wound, and allowed to slough off, by

which means the wound is kept free from feces for some days. If rectorrhaphy has been done the wound should be well flushed with sublimate, and a little iodoform dusted in, especially about the intestinal junction, before closing it. The insertion of one or two drainage tubes is of advantage. When the wound is left open a firm packing of either bicyanide or iodoform gauze forms the best dressing. This operation is naturally often followed by considerable shock, for which stimulants, a warm bed, assiduous nursing, and possibly strychnine, will be required. As yet the author has not had to transfuse, but it might be necessary.

With regard to after-treatment, there is nothing special to be said; that is, speaking of simple excision cases, he does not trouble about the bowels; if they remain quiet for a week so much the better, but as a rule a motion is passed before this, perhaps in spite of opium given to relieve pain. Most patients begin to get up and about after a month, and at the end of two are practically well. Some form of truss may have to be worn where there is either prolapse or incontinence, the latter being not infrequent where rectorrhaphy has not been successfully carried out.

A summary of fourteen cases which the writer details gives two deaths—that is, a mortality of a little over fourteen per cent.; two recurrences—one in two years and one in four months; ten living and well, of whom one is in good health after five years, two in good health after nearly three years, one after one year and nine months, three after one year, one after six months, and one after three months; one case has not been seen since leaving the hospital.

E. H. Taylor, of Dublin, in an excellent article in the *Annals of Surgery* for April of this year, states that the mortality of this operation is from twenty to twenty-five per cent., while Cheyne, in his lectures already referred to, estimates it at from eighteen to twenty per cent. He says: "The mortality varies considerably between the perineal and sacral operations, being naturally higher for the latter." In this Edwards agrees, for out of many cases of perineal excision he has not had a death. He further says that König's total mortality is 38 per cent., Billroth's 34, Kocher's 28, Albert's 18; Iversen's estimate of Kraske's operation 25 per cent., and Czerny's 19.4 per cent. He has not been able to find any statistics regarding the work of British surgeons. Ball, in the second edition of his

work, states that he has had four cases, which were all cured; and Littlewood's three cases have already been mentioned. Allingham, in his last edition, says he has performed the operation several times, but with what result is not stated.

#### *THE PROGNOSIS AND TREATMENT OF ACUTE GENERAL PERITONITIS.*

ABBE, in an interesting contribution on this subject appearing in the *Medical News* for May 29, 1897, concludes that a study of the initial signs in cases which have come to operation and been proved has shown him that uniformity of symptoms is entirely wanting. A persistent diffused spreading to the opposite side of the abdomen is very grave. A board-like stiffness of both sides of the abdomen is suggestive. Tenderness at a point in the rectum as high as the finger can reach in the median line is a sure index of either an inflamed appendix hanging over the pelvic brim, or an acute peritonitis. A pulse that is very rapid and quick, or "snappy," is almost a sure index of septic toxemia, and if it persists more than twelve hours, calls for interference.

Vomiting will usually occur once with most mild attacks, but if persistent indicates mischief. The tongue may be clean and moist and the eye bright in one-third of the cases of grave peritonitis, even after two or three days.

The facies of abdominal inflammation is more often a late symptom. Thoracic respiration is very often seen when spreading peritonitis prevails.

The temperature is frequently but little elevated during the first day or two, while the pulse may be showing great agitation.

These danger signals may serve to aid diagnosis before profound toxemia sets in—when the surgeon can do nothing.

Regarding treatment, substantial progress has been made in determining the lines of action.

There is but one opinion regarding the cleansing of the abdominal cavity when only the lower segment has as yet been invaded. The moment the surgeon sees septic fluid, he sponges it away before it can be scattered. He mops the presenting bowels with sponges in clamps, dripping wet with hot salt solution (one and a half drachms to a quart), and dries them again before drawing other coils into the field of inspection. As soon as parts are found not much inflamed,

he pushes a sterilized gauze tampon, properly folded, among the bowels far away from the field of work. This has a tape sewed to it, to which a clamp is fixed and left outside the wound. One or two such tampons may be thrust upward and across the abdomen before the pelvis is cleansed, to which much attention is always to be given. This being thoroughly mopped out, a light packing of mild iodoform gauze is to be placed in the pelvis, and a short way among intestinal coils elsewhere, especially if the gauze tampon now removed prove to have come out wet, absorbing the thin effusion from a distance. The abdominal wound should never be closed in any septic case. It wastes time, confines infection, and prevents drainage.

In the grave cases a long median incision or two lateral ones will always be needed. The lumbar drainage incision will only be necessary when the median cut is used.

The question of drainage has been thoroughly settled in favor of ample gauze packing, as against rubber or glass tubes.

The lymph barrier quickly thrown out by the peritoneum wherever the gauze is in contact at once forms a boundary line, beyond which one process is going on, namely, absorption, destruction, and elimination of the marginal infection, already entrapped, while at the site of packing the current is reversed, and everything is sucked into the gauze and removed.

When infection has been widespread there is but one alternative—irrigation. By flushing the intestinal spaces systematically with hot salt water, as hot as the operator's hand can bear (which will be over 105°, usually), these effects are produced. The water cleanses and stimulates the patient amazingly. One sees the pulse respond at once and remain steady long after the operation, and the absorbing power of the washed endothelium is diminished. This has been shown by experiments of Kinscherf on animals, where doses of strychnine or bichloride of mercury left after irrigation were not absorbed, while the same put into the peritoneum of dogs not irrigated were fatal. Thus the toxin absorption is temporarily arrested, while the patient fights for time to discharge the burden already taken up.

In the large abdominal incisions in bad cases, it is wise to leave the wound widely open. The gauze will hold back the intestines, and abdominal straps and binder will support the abdominal walls.

If the intestines are distended with gas and fluid feces it is well to let them come out of the abdomen, receive them in hot towels in charge of an assistant, and prick one or two prominent places with a knife to evacuate gas and noxious excreta, which is washed away with a constant hot stream. Through one opening there should then be injected a syringeful of saturated solution of Epsom salts, and the puncture closed. The author has done this on three occasions during the past three years, but only in the very worst cases.

McCosh, however, advises in all bad cases to pass such a dose of salts through an aspirating needle into the bowel, and close the aperture with one suture—which Abbe heartily endorses as a routine procedure. It cannot be vomited, it excites downward peristalsis, and as it aids to carry off impurities, it proves of the greatest value.

In regurgitation, lavage of the stomach should be done before and after operation, and repeated as soon as regurgitation is renewed.

The rectal tube to relieve distention by gas is of inestimable value, and its use not infrequently marks the turning point in the disease by promoting downward peristalsis.

Some of the most brilliant recoveries the writer has had have been where the attending doctor has been ineffectually plying the patient with calomel or physic, which acted only after operation, or where a good dose of calomel taken after operation has rid the body of all noxious excretions on the second or third day.

The value of an ice coil, or light broad ice bags, after a general peritonitis, cannot be overlooked. He has great faith in cold thus used to retard the inflammatory action and bacterial growth, either before or after operation. Moreover, it is almost uniformly grateful to the patient.

Strychnine—one-fortieth grain every two hours—is sometimes necessary, and in cases of severe pain when the patient is well out of ether, morphine hypodermically is rather helpful than otherwise.

Close study of bad cases of general peritonitis shows it to be one of the most absolutely fatal maladies with which we have to deal. It has also been demonstrated that logically and statistically the earlier the operation on the lines delineated, the better the prognosis. It has been further shown that even in the bad form, if operation be done and a masterly irrigation carried out, there

still remains a chance for life if the period elapsing be not more than two and one-half days. In cases where albumen and casts show in the urine it is proof enough that the system is already overwhelmed, and the kidneys and other glands are choked, and the operation hopeless.

The burden of responsibility for fatal issues in so many cases lies not with the surgeon so much as with those who withhold from him the opportunity to render the prompt aid which has been shown to be the only chance. The ideal success may be accomplished in the future not more by new methods than by new opportunities. The ideal operation may be the old method under ideal circumstances as to time.

#### *SUTURE OF THE LATERAL SINUS.*

The suture of large veins when wounded is a surgical procedure which very recently has come into practice, and like the ligature and clamp to control hemorrhage, was suggested by the exigencies of operations, attempts being made by surgeons to preserve the patency of large veins in order to obviate the disadvantages—perhaps death—which would follow their closure. Successful experiments upon animals have been reported from time to time during the last eight years, and many surgeons have obtained good results by suturing the axillary, femoral, internal jugulars, and other large venous trunks. One of the most interesting of these successes was the suture of the inferior vena cava by SCHEDE, after its injury in an operation upon the kidney. At autopsy, some time later, it was seen that the stitches had held perfectly, and that the lumen of the vessel was well preserved. But so far as known, SCHWARTZ records (*Gaz. Heb. de Med. et de Chir.*, Oct. 22, 1896) the first successful attempt at suture of the lateral sinus. His patient was a man, aged twenty-six, who presented himself with necrosis and a sinus behind the left ear, following a kick from a horse, received three months before. At the operation (November 24, 1895) a piece of bone the size of a silver dollar was found depressed. It was adherent in part to the dura mater, and despite every care the lateral sinus was opened during its removal, a rent nearly half an inch in length being made. Hemorrhage was profuse, but when two fine silk stitches placed in the wounded vein were drawn tight, the bleeding was controlled. The wound was lightly tamponed with iodoform gauze, and the patient

made a good recovery. The central portion of the depressed area of bone was necrotic, and it was at this point that the adhesion to the sinus existed.—*Medical News*, May 29, 1897.

*A CASE OF RIGHT OVARIAN HERNIA,  
WITH TWISTED PEDICLE: OPER-  
ATION; RECOVERY.*

The persistence of the canal of Nuck, the great mobility of the ovary, and its comparatively high position in young children, sufficiently account for the fact that the presence of an ovary in a hernia is decidedly more frequent during the first twelve months than in the whole of the rest of life. The following case, however, is chiefly noteworthy from the partial strangulation from torsion which the herniated ovary had undergone. The condition is very rare and undoubtedly difficult to diagnose.

This case is detailed by Mr. JOHN H. MORGAN in *The Lancet* for May 15, 1897: An infant eight months old was admitted to the hospital on March 9, 1897, with a lump in the right groin. There was no history of hereditary disease, but it was of interest to note that a brother had died from strangulated hernia. The infant had always been delicate, and ever since she was four days old a small swelling had been observed in the right groin. Four days before admission this swelling underwent great increase in size, the skin over it became red, and the parts appeared to be very painful, the child screaming constantly and drawing up the right leg. She was convulsed on two occasions, but had not vomited, and the bowels were quite regular. A medical man was consulted, who advised removal to the hospital. On admission the child appeared to be very happy and peculiarly free from symptoms. The temperature was normal. On the right side of the upper part of the *mons veneris*, extending over the right external abdominal ring, there was a rounded, semi-elastic, non-fluctuating swelling, which was not altered in size when the child cried. On attempting to elicit fluctuation pain was produced, and very faint pitting of the skin on pressure could be made out. The child was very fat, but on further manipulation an indistinct, rounded, irreducible body about the size of a cherry could be felt, which could be freely moved about, having as it seemed no connection with the interior of the abdomen. The bowels had acted naturally and there was no sickness. She remained in the same condition until the 12th, when

Mr. Morgan decided to operate, and having made an oblique incision over the swelling, he exposed a thin-walled sac in which some dark fluid was seen to be contained. A small incision through this membrane allowed the escape of about one drachm of bloodstained fluid, leaving exposed a smooth, rounded, plum-colored body about the size and shape of a small damson. Attached to the upper end of this, which on closer inspection proved to be the ovary, was a slender pedicle twisted upon itself to the extent of two and a half turns. This stalk was found to consist of the right Fallopian tube and the broad ligament, and upon pulling them further outwards the fundus of the uterus entered the wound. The portion of the twisted pedicle, almost to its attachment to the uterus, was in a congested condition similar to that of the ovary. A fine silk ligature was passed round the pedicle beyond the congested part and tied, and the ovary and pedicle were cut off, and the uterus was dropped back into the abdomen. A suture was passed through the external abdominal ring and tied, and the surface wound was closed with a continuous horsehair suture. The child recovered without a bad symptom and was discharged with the wound perfectly healed on March 24.

*EXTIRPATION OF THE LACRIMAL SAC  
IN CASE OF DACROCYSTITIS.*

ROLLET (*Lyon Medical*, No. 18, 1897) holds that the immediate results of excision of the lacrimal sac for dacrocystitis are excellent when the operation is complete. After union is obtained by first intention the cure is complete in about six days; the wound heals by granulation in about two weeks. The cicatrix is insignificant. As to the remote results, there are two rare complications, namely, persistent inflammation, necessitating a new intervention and due usually to incomplete excision or epiphora, possibly requiring ablation of the lacrimal glands. These complications occur in about ten per cent. of cases. Though at first sight epiphora would be expected as a rule, lacrimation gradually ceases, since the hypersecretion of the tears, incident to the inflammation of the sac, ceases.

The author gives a minute description of technique, and states that the operation is indicated when dilatation and the other means of treatment, persisted in for a reasonable length of time, have failed.

## VAGINAL DOUCHING.

GILES (*The Lancet*, May 15, 1897) states that vaginal douching has become such a universal practise, both in the hands of the public and under the supervision of medical men and nurses, that it may be well to review briefly some of the circumstances in which it is required, and the most suitable solutions under varying conditions. At the outset it is necessary to raise a protest against unnecessary and too frequent douching. The researches of Winter, Döderlein and others have shown that the vagina is normally inhabited by a benign bacillus, to which, through the formation of lactic acid, the acidity of the vaginal secretion is due, and the special rôle of which appears to be to antagonize and disarm of virulence any pathogenic organisms that may enter the canal.

Frequent douching of the normal vagina, especially with soapy and other alkaline solutions, tends to hinder or arrest this beneficent action and to destroy the guardian bacillus. Hence, under the circumstances, morbid conditions are provoked rather than prevented. The same argument applies to the practice of giving a vaginal douche before or during labor, for when this is normal the uterine and vaginal secretions, followed by the rush of liquor amnii, tend to sweep the passages in the most effective way—namely, from within outward. Secondly, it is necessary to protest against a long-continued use of very hot douches, whether in health or otherwise. Frequently, in inflammatory and other conditions of the pelvic organs, the medical attendant orders douches "as hot as they can be borne." These have their place, and an important one, for their effect in relieving pain and pelvic congestion is often most marked; but this is provided they be used only as a temporary measure. Not infrequently no later directions are given, with the result that patients continue these hot irrigations, perhaps twice a day, for months, and the means intended for cure becomes instrumental in prolonging and emphasizing the complaint, by inducing chronic pelvic congestion with its consequent leucorrhea. The remedy is simple—namely, that patients should be instructed to regard a hot douche as a temporary expedient, to be replaced as symptoms improve by tepid, cool, and even cold irrigations.

The use of a douche for purposes of comfort and cleanliness must be left in large measure to the discretion of patients; but

they should be warned of the harm that may result from its too frequent use, as stated above. Therapeutically, the douche is indicated in three sets of conditions: (1) after labor; (2) after vaginal operations; and (3) in the treatment of inflammatory conditions of the vagina, uterus, and appendages.

1. After labor. When the labor has been normal, with little or no intervention on the part of the attendant, and when the puerperium is also normal, it is open to question whether any form of douche should be used. In skilled hands no harm can result, and, in lying-in institutions it is probably an advisable routine procedure; otherwise it is probably better omitted. In cases of post-partum uterine atony or hemorrhage a hot douche is indicated, and when there is reason to fear septic developments a course of douching with mild antiseptics is desirable. In actual septic conditions one or repeated injections of stronger antiseptics may be required.

2. After vaginal operations. Here it is usually necessary to resort to vaginal douches for one or several weeks, either to keep the passages clear of blood, which would tend to decompose and so hinder the healing of wounds, or because there has been much manipulative interference. An aseptic or mild antiseptic solution generally suffices; at times, in septic conditions, a strong antiseptic is needed.

3. In inflammatory conditions. In these cases the douching is generally performed, not by the medical attendant or nurse as in the previous conditions, but by the patient herself or a lay friend. Hence more discrimination is required in prescribing potent solutions. Usually a bland solution is all that is necessary; in a few cases, as in gonorrhea, some stronger antiseptic may be temporarily required.

The fluids to be used for vaginal douching fall into three categories: (1) neutral or aseptic; (2) mild antiseptic; and (3) powerful antiseptic.

1. Neutral or aseptic solutions. Of these the first is plain or sterilized water. For the relief of pelvic pain and congestion this answers perfectly. If a more astringent solution be required we may use alum, one to two drachms to the pint; acetate of lead, one ounce to the pint; chloride of lead, saturated solution; and permanganate of potash (Condy's fluid) in weak solutions. This is one of the most generally convenient on account of its portability and ready solubility.

2. Mild antiseptic solutions. Among these we may mention: boracic acid or borax, two drachms to the pint; sulpho-carbolate of zinc, two to three drachms to the pint; carbolic acid, 1 in 80 to 1 in 40; tincture of iodine, one drachm to the pint; Cond's fluid, two drachms to the pint; cresol, 1 in 250; lysol, 1 in 250; corrosive sublimate or the biniodide of mercury, 1 in 5000; or chinolol, 1 in 8000. Of these, boracic acid, sulpho-carbolate of zinc, and Cond's fluid are perhaps the favorites when prescribing a douche to be used by the patient. Chinolol is comparatively a newcomer, but answers very well. Carbolic acid and iodine are useful for hospital administration. The poisonous character of corrosive sublimate is a contraindication to its indiscriminate use. For milder purposes other things answer as well, and in stronger solutions it should not be used except by the medical attendant. Lysol has the disadvantage of not being readily portable.

3. Powerful antiseptics. These are required after operations, and in obstetric practise, under septic conditions, and in the treatment of gonorrhea and septic conditions of the vagina and uterus. The most important are: carbolic acid, 1 in 40 to 1 in 20; iodine liniment, one to two drachms to the pint; corrosive sublimate, 1 in 1000 to 1 in 4000; and chinolol, 1 in 1000 to 1 in 8000. Of the first three we need not speak in detail, as their merits and demerits are well known. The desideratum is a material that shall be portable, readily soluble, non-toxic, and at the same time a powerful antiseptic. From this point of view a few words may be said about chinolol, which answers these requirements and which, being a comparatively new drug, may possibly not be familiar to practitioners in this country, though used a good deal on the Continent. It is a light yellow powder which belongs to the quinoline group, and is readily soluble in all proportions of water. It is non-poisonous, and for this reason it is especially suitable for use by patients themselves, and its antiseptic action appears to be considerable, being at least equal to that of corrosive sublimate. Where albuminous fluids are concerned chinolol appears to be superior to the sublimate, inasmuch as it does not coagulate albumen; corrosive sublimate, on the other hand, forms an insoluble albuminate of mercury, whereby the antiseptic action is interfered with. Chinolol resembles iodoform in appearance; and if it is intended to be used in dressings or on tampons, as a substitute for iodoform, the chinolol powder re-

quires to be diluted with boracic acid in the proportion of one part of chinolol to five or ten parts of boracic acid.

When strong antiseptic solutions are required for vaginal douching, corrosive sublimate, carbolic acid, and iodine should be used only by the medical attendant; chinolol for use by the patients themselves.

#### *SILVER WIRE AS A SUTURE IN SURGERY.*

Nearly half a century has elapsed since J. Marion Sims conceived the idea of using silver wire as a suture in the treatment of vesico-vaginal fistula. No sooner was the idea grasped than his fertile mind began devising ways and means for putting it into application, and a willing patient promptly submitted to its experimental use. After twenty-nine failures with various suture material, the thirtieth operation, performed upon this woman, proved permanently successful.

Not only was this the first case in which a cure was achieved by this distinguished surgeon, but it was the first successful operation for the relief of a vesico-vaginal fistula ever performed in the history of surgery. No wonder, then, that Dr. Sims attributed the brilliant result to the one new factor, silver wire; and no wonder, also, when similar results crowned his efforts in succeeding operations done with the same suture material, he stood ready to announce the edict that the use of silver as a suture was the great surgical achievement of the nineteenth century.

Undoubtedly the use of silver wire in those early cases, with only the crude appliances which he himself devised, and before anything was known of sepsis and asepsis in surgical work, was the factor which gave him success. Why it succeeded in the very cases in which silk suture had failed, was only explicable to him on the ground that silk acted as a seton, while silver did not. The immediate followers of Dr. Sims accepted his edict that silver wire was the only suture that could be used successfully in vesico-vaginal fistula, and used it without further inquiry into the rationale of its action.

As the operation became better understood, and specula and other instruments better adapted to their purpose came into use, operators in various fields were able to secure satisfactory results with suture material other than silver wire; so the sentiment gradually grew that Dr. Sims' success was due rather to the fact that he had better

facilities for doing his operation, and had attained greater skill, than to the nature of the suture material.

Within the past year, however, a satisfactory explanation of the success attending the use of silver wire as a suture has come most unexpectedly from a foreign source. Dr. B. Crede, attending surgeon to the Carola Hospital of Dresden, in an address delivered before the National Surgical Society of Germany, at its twenty-fifth annual convention, held in Berlin on May 28, 1896, discussed silver and its salts, the citrate and lactate, which he termed the itrol and actol, and pronounced them the most powerful of all the surgical antiseptics yet discovered. It appears that his interest in silver as an antiseptic grew out of the observations of his father, the elder Crede, on the value of the nitrate of silver in the treatment of inflammatory affections of the eyelids of infants. Nitrate of silver was not a success as a surgical dressing, however, on account of its chemical instability and its corrosive action on mucous membranes. While visiting the Johns Hopkins Hospital, in Baltimore, Dr. Crede was impressed with the use of silver foil as employed by Dr. Halstead, in affording an antiseptic covering for small or closed wounds. His next experiment, therefore, was made with metallic silver, using it as an antiseptic dressing for wounds. When applied to a sterile wound, he found that it remained unchanged, was non-irritating, and formed a thoroughly aseptic dressing. On the other hand, when applied to an infected wound, the products of bacterial life oxidized the surface of the silver, and, entering into combination with the argentic oxide, formed argentic albuminates which had powerful antiseptic properties. Careful analysis developed the fact that it was lactic acid which was developed in the microbic secretions, and when this combined with the silver oxide there developed a lactate of silver, and in this resided the antiseptic properties.

In this discovery lies the explanation of the value of silver wire as a suture. In aseptic, sterile wounds it is non-irritating and remains unchanged. In infected wounds it supplies in itself the base of a powerful antiseptic, combining with lactic acid, and forming thus in the tissues the lactate of silver.

The experience here recorded illustrates the principle so often insisted upon, that clinical observation has its legitimate field and is a faithful guide, although the scientific explanation of the conditions and results ob-

served are not, at the time, susceptible of a rational explanation. Sims' prophetic soul rested in the belief that some day a rational explanation of the fact he asserted would be forthcoming, and in this recent discovery of Crede it seems to be fulfilled.—*Medical News*, May 29, 1897.

*THE TREATMENT OF CHRONIC FRONTAL  
SINUSITIS AND CONSECUTIVE  
BRAIN LESION.*

BOTEY (*Annales des Maladies de L'Oreille, du Larynx, etc.*, No. 5, 1897) concludes a paper upon this subject as follows: In the case of frontal sinusitis with complete or partial retention of pus, the frontal sinus should be trephined promptly; having been opened, scraped and disinfected, communication should be established with the middle nasal canal by destroying the inferior wall of the sinus and by enlarging the nasal frontal canal. Thus the cavity is drained without requiring the use of a tube, and the opening may be closed. When cerebral troubles develop, such as somnolence and vomiting, etc., perforation of the posterior wall of the sinus may be suspected, with penetration of pus into the cranium. Under such circumstances the posterior wall of the sinus should be opened freely, the granulations should be scraped away, the dura mater should be thoroughly cleansed and explored with a trocar thrust into the encephalon—a procedure without danger if antiseptic precautions are observed. The lesion is curable if the cerebrum is not involved, and even if inflammation has extended to this structure cure can be expected, provided the intervention is speedy and bold. In case of obstruction to the naso-frontal passage, and the perforation of the posterior wall of the sinus, with or without cerebral hernia, the frontal wound should not be closed, since infection may then travel from the nose. The cerebral substance should not be irrigated either with sublimate or carbolic acid, but with a sterilized solution of boric acid.

---

*OPEN MEASURES IN THE TREATMENT  
OF SO-CALLED SIMPLE AND COM-  
POUND FRACTURES.*

OSCAR H. ALLIS in the *Annals of Surgery* for June, 1897, publishes a practical and interesting contribution to the literature on this subject.

He states that all conceivable fractures were formerly divided into two general

classes, simple and compound. If the skin were not broken—or if broken, if the wound did not communicate with the seat of fracture—the injury was denominated a simple fracture, in contradistinction to all other fractures in which a wound in the skin communicated with the seat of fracture, and this class was called compound.

The treatment for the simple fracture was to approximate the fragments, immobilize them, control undue tendency to inflammation, and finally, with repair, to reestablish the function of the limb.

The treatment of compound fractures was to immediately convert the compound into a simple fracture, and proceed as with simple fractures. Should there be a protruding fragment which resisted all efforts at reduction, saw it off and close the wound. Thus, in a few crisp, axiomatic sentences, the treatment of the whole range of fracture-injuries was placed within the grasp of the student.

There are few who will read these lines that cannot verify their accuracy, and none who read them can instance a greater contrast in the treatment of any surgical affection than the treatment just rehearsed—*i. e.*, the treatment of fractures in former times—compared with their treatment to-day.

Let us take as an example a fracture of both bones of the leg. There is a small wound communicating with the seat of fracture, half or a quarter of an inch in length. The surgeon of to-day cleanses the skin and surrounding parts, isolates the field of operation, freely enlarges the wound in the skin, superficial and deep fascias, until he reaches the seat of fracture and can inspect as well as explore the region of injury. If there are fragments of bone he removes them, if they are likely to interfere with repair; if there are bleeding vessels he secures them. Then, with the best possible exposure of the part, he washes it with pure or medicated water until he has cleansed it of all pollution; and, finally, secures coaptation, not by the awkward and unsatisfactory medium of splints, but by direct coaptation by means of screws, pegs, or some approximating material. Then, without even approximating the soft parts by sutures,—or if at all, but loosely,—the wound is dressed with sterile materials best adapted to absorb any exudation, and the whole enclosed in a plaster-of-Paris dressing and swung from a cradle, or placed upon a soft pillow.

Result, one dressing, and only one, from first to last, and with the removal of this, at

the expiration of six to eight weeks, the wound has closed, the bones have united, and the patient is well. No greater triumph for modern surgery!

Contrast such a case with the not infrequent result of a compound fracture in former days. Though the wound healed promptly, swelling soon began to extend from ankle to knee, pus dissected its way through all the parts, until finally an opening was made either spontaneously or by the surgeon, and a pint of pus found exit. Then followed the long term of healing, the wasted muscles, necrosed bone, with often, as a final result, the amputation of the limb as the best possible compromise.

Right here one is met by the interrogatory, Does any one treat compound fractures to-day as they were treated a score of years ago? Is not the student everywhere taught to sterilize the wound and surrounding parts and dress it antiseptically? The answer is Yes; but what the author claims is that the student has learned but half a truth. He regards the wound as an infected wound, but he fails to realize that at the deepest part of that wound—the parts surrounding the fragments of bone and periosteum—his disinfectant cannot reach, and that with all his care in dressing he has done little more for the unfortunate man than was done in pre-Listerian days. What hospital surgeon cannot bear testimony to the accuracy of this statement? What surgeon has not been told on entering his wards that a case of compound fracture has been admitted, the wound syringed out with bichloride, sutured, and dressed antiseptically, and the whole immobilized? And all this is said with an air that betokens a full up-to-date appreciation of the proper thing to do! Some of these cases will do well, and the same is true of some compound fractures treated a score of years ago.

Take a similar injury to the leg, both bones broken but the skin intact. What is the condition? It differs from the former in only one respect, *viz.*, it is not directly infected. In every other respect they are identical. The same laceration of periosteum, deep and superficial fasciæ, the same outpouring of blood between the fragments and muscles, the same displacement of bone fragments. And the question arises, How shall we proceed? In precisely the same way as if the skin were broken. Open up the part with a free incision, carefully divide the deep fascia to the full extent of the seat of frac-

ture, or, better, to the full extent of the external wound; then cleanse the wound of clots, ligate bleeding vessels, repair injured nerves, wire or directly immobilize the fragments, dress without suturing, and encase in plaster as before.

Dr. Allis does not wish to be understood as resorting to open measures in all simple fractures. Such an impression would be very foreign to his honest convictions, as well as to sound surgical practise. What he urges is that very many so-called simple fractures are as grave as the more dreaded compound fracture, and cannot possibly be scientifically treated by other than open measures. Open measures are often unnecessary, would often be injudicious, and yet he claims that they are the only measures that are entitled to the term scientific.

This brings us naturally to the question, Should the terms "simple" and "compound" be retained in classification of fractures? In the light of modern surgery, when there is every rational ground for open measures, shall the term "simple" be retained?

This term has a meaning to the patient, to a prosecuting attorney, and to a jury, that may be foreign to the lecture-room. When a limb shrivels from a pierced nerve, or dangles like a flail from non-union, it reacts with overwhelming force against the attending medical officer. When it is said that he assured the patient, as he undertook the case, that it was only a simple fracture, the argument is that if it had been a simple fracture it would have healed, but through the ignorance of the doctor a very serious fracture had been mistaken for a simple fracture. Nor is such a charge chiefly to be preferred against the general practitioner. It can with equal justice be said of the hospital surgeon. Whoever treats a fracture with unbroken skin must confess that he has treated it ignorantly. Allis has seen six fractures of the elbow-joint, all simple, that resulted in total loss of function of the forearm and hand, and one of them occurred in the hands of Philadelphia's foremost hospital surgeons. Nor was there any evidence of the gravity of the original injury in any of the cases to create a suspicion on the part of the medical attendant of so serious a result. The writer within two years has had two cases of non-union of fracture occur in his own practise, both simple, both under his complete control; the one a femur, the other a humerus. And when later he resorted to open measures he found the cause of non-union to be muscle interposed between

the fragments, a condition that could not possibly be detected by palpation and manipulation at the time of setting the limbs, though both were set under the influence of an anæsthetic. There is nothing simple about a fracture from a surgical standpoint, and, furthermore, as a definition it is both misleading and impolitic, and should be abandoned.

In the selection of substitute words no one can tell what will become the most popular. The terms "open" and "closed" have been advocated; they are certainly easily spoken, easily remembered, familiar, and not open to the objection that they are misleading. To the author's mind, better terms, though less familiar, are "infected" and "non-infected."

#### *SUCCESSFUL SUTURE OF A PENETRATING WOUND OF THE HEART.*

At a recent meeting of the German Surgical Society REHN (*Deutsche Med. Woch.*, May 6, 1897, p. 88) reported the case of a man twenty-two years old who was stabbed with a knife in the left chest and came under observation in a most unfavorable condition, with dyspnea and cyanosis, almost pulseless, and covered with blood. A wound was found in the left fourth intercostal space. The area of cardiac percussion dulness was increased to the right; the heart-sounds were clear. On the following day the condition of the patient had improved, but the area of cardiac dulness had increased. On the third day the condition had grown worse, the pulse failing and the respiration becoming greatly accelerated. The area of cardiac dulness had increased still more and the patient appeared moribund. Operation was decided upon, and an incision was made in the fourth intercostal space, the fifth rib also being divided, and the pericardium exposed. When the wound in this sac was enlarged a large clot was encountered, and an incised wound of the right ventricle 1.5 centimeters long was found. No blood escaped during systole, and it was possible to compress the wound with a finger without embarrassing the action of the heart. Three silk sutures were introduced during diastole and the hemorrhage ceased. The pleura was irrigated with saline solution and, together with the pericardium, packed with gauze. Immediately after the operation pulse and respiration were better. The surgical progress of the case was complicated by purulent pleurisy, necessitating later reopening of the pleura. Except for slightly increased activity of the heart, the condition

of the patient was an excellent one seven months after the accident.—*Journal of the American Medical Association*, May 29, 1897.

#### SURGICAL SIGNIFICANCE OF GALL-STONES.

Dr. F. LANGE, before the Johns Hopkins Hospital Medical Society, offered the following as the outgrowth of a large experience in the treatment of hepatic calculus: In operating, his preferences have led him to entirely abandon the longitudinal incision; but, according to the proposition of Covisart and the experience of other surgeons, as reported in the *Hospital Bulletin*, he further says he does exclusively the operation parallel to the border of the ribs. Correspondingly to the thickness of the abdominal wall, this incision must occasionally be a very large one. A very great difficulty must occasionally be met with through the smallness of the liver. It is a mistaken idea that in consequence of stagnation of bile the liver must be enlarged. On the contrary, he has had the experience that in occlusion of the common duct of long duration, probably through the influence of pressure, an atrophic condition of the liver-tissue will take place, and occasionally the liver will be concealed high up behind the ribs, and this may cause a great deal of difficulty in consequence of the high and deep position of the field of operation. In eight of these cases he has excised the adjacent cartilages of the ribs, and he would like to commend that. It facilitates the operation very much. On the other hand, the enlargement of the liver may be a great hindrance, and especially in fat and plump persons of short build, it may be quite difficult to get down to the common duct. In one of the cases he was unable, in spite of the excision of the ribs, to get effectually down to the point of the trouble, and not until he had pulled the liver out of the incision as far as he could—almost one-third of the liver substance being brought outside of the abdominal wall—was he able to easily get to the cystic and common ducts. In this case he was obliged to open the cystic duct at two different points, and besides that, the common duct at the usual place about the middle of its course. In the cases of acute inflammation it is necessary, whenever one has reason to presume that the neighborhood of the gall-bladder is infected, to keep everything as open as possible and give entirely free outlet for the peritoneal

secretions. At the same time he always drains the gall-bladder with a long tube, with the view of having a siphon action upon the secreted gall, and this will act very effectually. Occasionally a blockade will take place through mucus or blood clot, and then it will be necessary to change the tube or make a cautious washing through it. He would advise against the injection of any irritating antiseptic solution into the gall-bladder. He has observed that occasionally this fluid will cause distressing symptoms, attacks of colic, probably because it may get into the common duct and the hepatic duct and cause irritation. He only uses saline solution or boiled water. He has always found that the bile itself was an antiseptic agent. After a short time the amount of purulent secretion is insignificant, and the healing of the abdominal wounds, although constantly in contact with the bile, is mostly uneventful and without any untoward symptoms.

About stones in the liver substance he has no practical experience. He once found a stone in the liver after it had perforated the walls of the gall-bladder, but he has not had any experience with stones in the liver that have formed in the gall-system above the hepatic duct. It is a fact that these stones will occur—that occasionally quite extensive casts of stone formation will take place in the gall-system. He does not mention comparatively frequent uncomplicated cases, where we have to deal with dilated gall-bladder and stones, and where the surgical treatment is comparatively simple. He never does the operation in two sittings. He finds that it is entirely safe to operate in one sitting. He has always aspirated as much as possible of the contents of the gall-bladder through a thick aspirating needle, protecting the surroundings as cautiously as possible to guard against infection.

He thinks that in some of his cases he has reason to assume that there is some valve action, especially in one case of stone in the common duct, of small size. The patient had had an attack of gall-stone some three months before this attack, with jaundice lasting several weeks, most likely because of obstruction from this stone, which was solitary, as judged by its very round, regular shape. Probably after a time this stone shifted back, and later on again caused obstruction, together with an infection. This we see not uncommonly in cases of obstruction of the common duct. Even if the stones are ball-like or rounded, at intervals a certain amount

of bile will get into the gut. It is almost characteristic that if, in prolonged jaundice, at intervals the condition of the feces and the urine points to the passage of a certain amount of bile through the duct, we have probably to deal with obstruction from stone. Regarding the drainage of the common duct he has tried everything; he has left the duct entirely opened, and has sewed it up with the insertion of a small drainage tube into the lumen of the duct, and he has sewed it up entirely. In cases where the common duct is healthy he thinks it preferable, if it can be done, to sew up the duct entirely. If there is reason to assume that there is obstruction beyond the stone, he would prefer to drain, and he does this in such a way that he inserts a small drainage tube from the wound in the common duct and packs gauze around it. This gauze (iodoform gauze boiled in glycerin) he leaves in for five or six days. The tube he leaves for a sufficiently long time to secure the proper outlet of any secretion as long as it exists. In draining a gall-bladder he packs the gauze around the tube and leaves the opening comparatively large, for the reason that, at least in inflammatory cases, the surface of the gall-bladder is such that it will necessitate some thorough cleansing and local treatment for a limited time. There will be clots of blood or shreds of tissue or inspissated mucus which might easily obstruct. He mostly removes this tampon in two or three days, and gives the inside of the gall-bladder an additional thorough washing and cleansing. Besides this he has either sewed the peritoneum to the surface of the gall-bladder where there was no infection outside of it, or he packed around the circumference of the gall-bladder in such a way that even if some of the contents of the bladder escaped it was not likely to cause a spreading inflammation. A very serious complication that has led to fatal issue in several of his cases of advanced cholemia is an inclination of the patient to bleeding. Three of his cases he has lost from secondary hemorrhages. Two of these cases were complicated with malignant disease of the pancreas. Necropsies were not made, and he could only say that he felt in the region of the head of the pancreas a resistant hard mass which he took for malignant affection. Lately Professor Riedel, a surgeon who has perhaps worked more in gall-surgery than any other man living, has published cases in which he is inclined to assume that occasionally these apparently malignant thickenings of the pancreas may be

but inflammatory thickenings, and he mentions one case which seems to be beyond any doubt. In an elderly gentleman, in whom the operation was abandoned, assuming that this was a case of cancer of the pancreas, the stones merely were removed. A fatal issue was awaited, but the patient lived for years and became healthy and strong, and there could be no question about his not having malignant disease. He assumes that through the presence of stones an irritation is kept up in the pancreas, and that this irritation, after the removal of the stone, may cease and the condition improve. The author lost one of these cases by the separation of the Murphy button after establishing cholecystenterotomy. The patient had up to that time had small hemorrhages from the inside of the gall-bladder. The author purposely kept the gall-bladder open, stitched to the abdominal wall, because he had the impression that this would probably be a case of bleeding, and in order to tampon and make counter-pressure he kept the gall-bladder open and was able up to the tenth or eleventh day to check the bleeding, but after the separation the patient had a profuse hemorrhage into the large intestine, and succumbed to anemia.—*Journal of the American Medical Association*, May 29, 1897.

#### *THE USE OF CANTHARIDES AS A REMEDY FOR ANASARCA.*

MYSZYNSKA (*Gaz. Heb.*, 11 Av., 1897) states that the use of cantharides as a remedy in anasarca is of extreme antiquity, dating back to Hippocrates. Encouraged by the results of Cazal, who in 1895 reported five absolute cures of acute nephritis by means of tincture of cantharides, the author made use of Barth's service to investigate the effect of this drug in diseases of the kidneys. He first treated ten cases of acute nephritis, administering the drug in doses of from six to eleven drops given in a glass of milk. In the first case persistent albuminuria in a person affected with malaria was completely and rapidly cured. The next case was one which had resisted treatment for seventeen months, the patient being tuberculous. This patient was greatly improved, the tubercular lesion cicatrizing. Three other cases were markedly improved, but disappeared before treatment could be completed. In two pronounced cases complicated by marked arterio-sclerosis, albuminuria was increased by the drug and the symptoms were aggravated. In two other cases of marked nephritis no other effects

were observed. In one tubercular case albuminuria was increased and the temperature was unfavorably affected. In eight out of the ten cases treated by tincture of cantharides diuresis was markedly increased. In all the patients the appetite was markedly increased, sometimes to an astonishing degree, and was not accompanied by any digestive troubles.

The author concludes that cantharides is a remarkable diuretic and a powerful drug in the treatment of refractory albuminuria, especially in recent acute nephritis. It should be given with periods of repose, and should be avoided in cases of arterio-sclerosis.

*INJECTION OF ANTISTREPTOCOCCIC SERUM  
IN CASES OF OPERATION  
INVOLVING SUBSEQUENT  
SEPSIS.*

WATSON CHEYNE (*Practitioner*, April, 1897, p. 347) accounts for the great variation in the reported results of the treatment of septic trouble by antistreptococcic serum by the acute character of the diseases set up by the streptococcus pyogenes; irremediable damage is done to the body before the immunizing material has time to produce its effect, or, as in two of his own cases, though the local process is arrested the general temperature is not improved, nor the life of the patient preserved. Experimental evidence is strongly in favor of the prophylactic action of injections of antistreptococcic serum; he thinks their use should not be confined to cases in which infection has already occurred, and that it is in prophylaxis that they will be found most valuable, and especially in operations about the tongue or throat in which septic pneumonia engendered in most if not in all cases of the streptococcus pyogenes is frequently the cause of death. In a recent case of carcinoma involving the base of the tongue, the anterior pillar of the fauces, the tonsil, and also the large glands in the anterior triangle of the neck, Cheyne, on the two days before operating, injected twenty centimeters and ten centimeters of antistreptococcic serum; and after a preliminary tracheotomy extirpated the glands, ligatured the external carotid, split the cheek, and removed the diseased parts of the mouth and throat. Ligature of the external carotid greatly facilitates such an operation and diminishes the immediate danger, but is a very fatal proceeding owing to sloughing and secondary hemorrhage. Here

there was nothing of the kind. The progress of the case was very remarkable; after the first twenty-four hours there was no elevation of temperature; a rise, evidently an after-effect of the serum, occurred some days later; there was no septic pneumonia, no tendency to septic infection, no inflammation, no sloughing of the surface of the wound; there was an almost entire absence of smell in the breath. Healing was quite uninterrupted. In a case of malignant disease of the left side of the lower jaw, inside of the cheek, and anterior pillar of the fauces, and extending to the alveolar process of the upper jaw and some small cervical glands, injections of twenty centimeters were made on February 15 and 16, and one of ten centimeters on the 17th, a few hours before the operation. The skin healed by first intention, and the wound in the mouth rapidly granulated without any sloughing; there was no elevation of temperature after the first twenty-four hours, and then it did not exceed 100.4°, and the case was most striking from its absolute freedom from septic complication. In a third case, after preliminary extirpation of a large mass of glands from the neck, ninety centimeters was injected during the four days preceding the removal of the tongue. There was the same freedom from septic trouble, and the same absence of smell, and everything promised well till the patient suddenly expired. An embolus detached from a thrombus in the lingual artery, which had extended into the carotid, had lodged in the brain. Though a certain amount of sloughing was found at the back of the wound, the greater part was quite clean and free, and there is no reason to doubt that but for this unfortunate accident healing would have been uninterrupted. Extensive operations will be far more feasible if the septic pneumonia and the diffuse septic processes so apt to follow them can be prevented by the prophylactic use of antistreptococcic serum.—*British Medical Journal*, May 15, 1897.

*COLLES' FRACTURE.*

Dr. STORP (*Archiv. f. Klin. Chirurg.*, bd. 53) employs a simple method of treatment which is essentially the same as was advocated many years ago by Sir Astley Cooper.

Storp has treated one hundred and four patients in this manner: A strip of rubber plaster 2½ inches wide is wound about the arm just above the wrist-joint. A second piece is placed exactly over the first, a fold

being made in it on the radial side, which stands out far enough from the arm to allow a large hole to be made in it. Through this hole a string is passed, and the arm is held high up on the chest, the hand dropped downward toward the ulnar side. The treatment is at first rather painful, but if the arm is kept high up venous congestion is avoided, and the pain becomes much less. The plaster is removed in ten days and the hand simply placed in a sling, while the patient is advised to use it carefully. In a few of Storp's cases in which there was extensive hemorrhage massage was employed. The average duration of treatment was three weeks, while fourteen to eighteen days sufficed in patients under twenty years of age. The results were exceptionally good. Of the ninety-five cases in which directions were carried out, the arms of ninety-one were completely restored in appearance as well as function; in four the functional result was good, but there was a slight radial deformity in three cases, and a rather marked radial deformity in the fourth. —*International Journal of Surgery*, June, 1897.

#### ANESTHESIA OF THE POSTERIOR URETHRA.

SCHARFF (*Centralblatt für die Krankheit der Harn. u. Sex.-Org.*, vol. 8, 1897) states that the posterior urethra can be rendered absolutely non-sensitive by the following rectal injection:

- ℞ Morphine hydrochlorate, 3 grains.
- Atropine sulphate, 1-10 grain.
- Distilled water, 2 fluidounces.

From half a drachm to a drachm of the solution made in these proportions is injected into the rectum.

#### HEPATIC FISTULA SUCCESSFULLY CLOSED AFTER SIXTEEN MONTHS.

MOIR reports the following case in the *British Medical Journal* for April 24, 1897:

An Armenian aged twenty-seven years, while employed in railway construction at Selangor in the Straits Settlements about the middle of December, 1893, began to suffer from what eventually proved to be an abscess of the liver. He was admitted into hospital at the end of January, 1894. Early in March he was operated on for an abscess of the liver. Six weeks later he was discharged apparently cured, the wound having closed. He sailed for Singapore, but the

wound reopened on the voyage, and there was a copious purulent discharge. On arrival at Singapore he went into hospital, and a drainage-tube was inserted. The wound was again healed by the end of June. After remaining six weeks longer the sinus reopened and again began to discharge pus. Accordingly he sailed for Calcutta, and was admitted into the hospital on September 4, 1894. No antecedent history of dysentery or drink could be elicited. On admission he was in rather a reduced condition, weighing only 123 pounds. The liver was of natural size, but there was a hepatic fistula discharging unhealthy pus in the eighth intercostal space and pretty far back into the infra-axillary region. On September 6th the first attempt to close the sinus was made. An incision was made to explore for dead bone, but the ribs were quite healthy. After a little manipulation the fistula was found to be very narrow, slightly tortuous, and six inches long. Its track was dilated so as to admit a long and narrow drainage-tube. On the 10th the patient was transferred to Moir's wards and continued as his patient until he finally left the hospital in October, 1895. Syringing with iodine lotion and insufflation with iodoform were tried, but ineffectually. Then on September 28th, 1894, an inch and a half of the eighth rib was resected in the region of the fistula. The channel was over six inches, very narrow (admitting only a fine probe or a knitting needle), and had dense walls which felt almost cartilaginous in consistence. In its course the fistula traversed the pleural cavity (the pleura being adherent around it), the diaphragm, and a considerable thickness of liver tissue near the upper surface of the right lobe. The track was dilated gradually with some difficulty, until finally a cavity was reached. The finger could just reach this cavity; but it was estimated, with the help of instruments, that it was about the size of a hen's egg, and that it had thick walls. A collection of pus, caseous material, and sloughy tissue was removed by a long-handled Volkmann's spoon. A drainage-tube having a diameter of three-quarters of an inch was inserted. For the next two or three days the patient suffered from acute epigastric pain, nausea, and vomiting; but after October 1st, there was no further trouble. Up to the end of November his physical condition was good, and he weighed 138 pounds, having gained over a stone; but the fistula would not heal, and at this time was two and a half inches long.

Although the discharge had become scanty it frequently contained bile and mucus for several days at a time—and the bile seemed to retard healing. Various solutions were tried for syringing the fistula—*e.g.*, carbolic acid, perchloride of mercury, boric acid, thymol, iodine, iodoform in ether, and sulphate of zinc. The tube was gradually shortened, then smaller tubes were substituted, and finally when the fistula narrowed a strip of lint was inserted. Bark and ammonia and hypophosphites were given, and on several occasions sponge grafting was tried, but nothing succeeded. In December he began to lose ground again, and the length of the fistula varied from three to four inches. The discharge contained flaky pus, occasionally bile, and tenacious glairy mucus. The wound was syringed twice, sometimes thrice, a day. This improved the character of the discharge. On December 18th an incision was made through the former cicatrix, and the fistula was slit up and dilated. The cavity was now smaller and more shallow, and so could be better explored by the finger. The dense connective tissue lining the walls of the fistula and cavity for the entire length of the track was thoroughly scraped with a Volkmann's spoon and the debris removed; then the entire raw surface was well swabbed with a solution of chloride of zinc (forty grains to the ounce) and a large drainage tube was introduced. This operation was not attended with any serious hemorrhage. That night and next day there was cough, bilious vomiting, and epigastric pain. The drainage-tube seemed to irritate the diaphragm, but after the first two days he had little pain or discomfort. In January, 1895, he began to improve again. The fistula became smaller and the discharge less; but still the dressings were often bile-stained. Quinine and iron, nitro-muriatic acid, and nuxvomica were administered. During February his general health was excellent, but the fistula remained much the same. Syringing and insufflation were discontinued, and a probe covered with cotton-wool and dipped in compound tincture of benzoin was daily inserted in the fistula. This proved more efficacious than anything hitherto tried; still, the track would not close, and the discharge contained bile at intervals. In March the same treatment was continued and the discharge almost ceased, but the fistula was still nearly two inches in depth, so on March 22d he was sent on a voyage in the hope that the change and sea air might prove beneficial.

He returned to hospital on May 24th. The trip had apparently done him more harm than good. He looked worse and said he had felt miserable all the time that he was at sea. The sinus was two and a half inches long and had been constantly discharging bile, mucus, and pus. His weight was 131 pounds. He was given a tonic mixture, the wound was dusted with alum and iodoform, and a dry dressing of perchloride of mercury was applied. Early in June minute particles of nitrate of silver were inserted into the fistula, which remained about two inches long and continued to discharge bile occasionally. His weight rose to 136½ pounds. On June 8th a probe heated red-hot was introduced and the walls of the track were thoroughly cauterized. This was the only operation which was followed by fever, and the febrile reaction was severe. Next day his temperature rose to 102° F., on the following day it varied from 100° to 104.2°, on the 11th from 101° to 104°, and on the 12th from 101.8° to 105.4° F. He was very restless and suffered from intense headache, and the discharge was profuse, greenish, and viscid. On that day he developed acute orchitis and epididymitis without any obvious cause. This was treated by free leeching and an evaporating lotion. By June 18th the fever had quite left him and he again began to improve, but the fistula had increased to three inches. The right testis remained large, and on the 22d fluctuation was discovered, and his temperature again began to rise. An abscess in the globus major of the epididymis was incised and drained. He was given a mixture of strychnine and iron, with sulphate of magnesia occasionally, and powdered boric acid was applied to the fistula, and a dry dressing. Early in July an emulsion of eucalyptus oil was injected into the fistula, which was again two and a half inches long. The track began to contract rapidly, and by July 8 the fistula was occluded and there was no discharge. The fistula soon firmly healed and subsequently gave no further trouble. He remained under observation until September 16, when he was discharged feeling perfectly well and strong. But four days later he was readmitted suffering from an anal abscess, which was incised on the day after admission and the wound healed readily. He was finally discharged on October 7, 1895, at which time the scar of the hepatic fistula was quite firm and the liver seemed sound.

This case is of some interest owing to its

obstinate course, to the number of operations performed, and to the intercurrent complications. The persistence for sixteen months of a hepatic fistula, after an abscess of the liver was opened, illustrates the evil of the too early removal of the drainage-tube. Probably, also, too small a tube was used in the first instance. For the drainage of an abscess of the liver the larger the tube the better, and there should never be any hurry to dispense with the tube. *Festina lente* is just as important a principle in the after-treatment of an abscess of the liver as is the avoidance of delay in operating when once the abscess has been diagnosed. Quite a variety of causes were at work to prevent the closure of the fistula: (1) There was the absence of surgical rest owing to the cavity and fistula having such close relations to the diaphragm, a muscle which is never at rest; (2) the course of the fistula was somewhat tortuous through the various layers of liver, peritoneum, diaphragm, pleura, intercostal muscles, and skin; (3) there resulted consequently an ill-drained cavity at the end of a long and sinuous passage, which would not heal owing to retained sloughs; (4) the escape of bile and mucus from time to time through the fistula caused irritation and retarded union; and (5) the chronic nature of the case tended to further the formation of a lining of dense cicatricial tissue in the walls of the fistula, which, until it was destroyed, of itself precluded the possibility of closure.

---

*EXTROVERSION OF BLADDER TREATED  
BY LEFT NEPHRECTOMY AND  
TRANSPLANTATION OF THE  
RIGHT URETER THROUGH  
THE LOIN.*

REGINALD HARRISON (*Medical Record*, May 1, 1897) details an interesting case.

The subject of the treatment the author is about to describe is a boy now aged fifteen years. He is the victim of a congenital extrophy of the bladder and an epispadiac penis with the pelvic cleft. He first came into hospital in July, 1895, for the deformity mentioned. There was a considerable protuberance of the posterior wall of the bladder, upon which the orifices of the ureters were distinctly visible. The exposed mucous membrane was very sensitive, and readily bled upon being touched either by the hand or by the clothes, and the thigh and legs were much excoriated by the constant dripping of urine from above. The patient's condition

was a very miserable one, and he was much emaciated on his admission to the hospital. Shortly after his reception he showed signs of having contracted scarlet fever, and was consequently removed to a hospital for infectious diseases. For some weeks after this his urine remained slightly albuminous.

On his readmission, after satisfying himself that both kidneys were in good working order, and the urine healthy, on January 17, 1896, Harrison removed the left kidney by lumbar incision. The patient recovered rapidly and completely from this preliminary operation. With the view of allowing ample time for the purpose of enabling the remaining kidney to grow and to provide for the entire urinary excretion, the patient went home for some months, occasionally returning for observation.

He was again admitted to the hospital in November, 1896. His legs and thighs were still much excoriated by the constant dripping from the single ureter, and the protruding mucous membrane of the posterior wall of the bladder remained scarlet and sensitive. Repeated examinations proving that the excretion of urine had been effectually carried on by the solitary kidney during the period of nearly eleven months which had now elapsed since the preliminary nephrectomy, the right ureter was transplanted on December 5, 1896, in the following manner:

A flexible bougie was passed up the solitary ureter so as to serve as a guide for finding the canal as it crossed the brim of the pelvis. A small incision was then made in the right loin on the same lines as if for a lumbar colotomy. By a little deep dissection the ureter was readily found and exposed. A carbolized silk ligature was placed upon it just below where it crosses the common iliac artery, and the tube was then cut across on the kidney side of the ligature and brought out into the loin wound. To the latter it was attached by one fine silk suture. There was very little bleeding and the whole proceeding occupied only a few minutes. The loin wound was partly closed by a suture at either end, but not so as to occlude the ureter. Before the patient left the operating-room urine was seen issuing from the transplanted ureter. A pad of absorbent material over the wound completed the dressing. It was noticed that, as the ureter was being transplanted, retching and attempts to vomit became continuous.

The patient also vomited at frequent inter-

vals for twenty-four hours after the operation. This immediately ceased at the expiration of this period, when in the course of his usual visit to the hospital Dr. Harrison removed the little suture which attached the divided end of the ureter to the loin wound, and which had evidently been keeping up some tension on the former. The now disused and protruding posterior wall of the bladder was covered with lint and vaseline, and the patient was placed on a light but nutritious diet.

For ten days after the operation the patient's condition was in all respects most satisfactory, the discharge of urine from the loin wound being, as far as he could judge, free and normal. Then followed a series of high temperatures, which continued from December 16 to January 29. On December 23 the temperature was 105.3° F., while on December 24 it fell as low as 97.4° F. These variations continued up to January 29, when the normal level was again maintained. No rigors were noticed, though there was sweating and occasional vomiting. At times the patient was evidently drowsy, but he seldom complained of feeling ill and was generally in good spirits and took his food with appetite. On January 7 he was allowed to get up on a couch, and since that date he has steadily improved in every respect.

Different causes were assigned for these variations in temperature. At first it was thought that they were due to influenza. Then it was suggested that some suppuration was going on. But the evidence was insufficient. The urine as collected from the ureter was clear and contained only a slight trace of pus, which was probably derived from the external wound. It seemed more likely that either the eliminating function of the kidney had been disturbed, or that these variable temperatures were due to changes directly connected with the absorption of the unused mucous membrane of the bladder, which was now rapidly going on. It is to be regretted that at this stage no qualitative examination of the urine was made, which might have thrown some light upon the point.

The boy was greatly benefited by the change in the mode of urination. He is able to maintain the erect position, and moves about comfortably, being quite free from excoriations about his thighs and legs. His general condition is also much improved. Nothing has yet been done to close in the posterior wall of the bladder, as it appears

to be slowly undergoing a process of cicatrization. It would, however, be quite easy to effect this by a plastic operation, now that the surface of the bladder wall is no longer in contact with the urine.

Harrison calls attention to the difference in the condition of the urine trickling from the ureters in these deformities, mixed with the abundant glairy excretion of mucus from the surface of the exposed membrane of the fissured bladder, as compared with the excretion that escapes from the artificial fistula in the loin, as in this case. In the former instance the excretion is irritating and offensive, with a strong tendency to form phosphatic calculi upon nuclei provided by the pubic hairs; while in the latter these characteristics are absent, and the presence of the patient ceases to be in these respects a cause of offense to others.

Though in this instance the treatment was undertaken solely with the object of ameliorating the patient's condition, it is possible that a similar proceeding, or some modification of it, might be utilized in connection with the treatment of other forms of urinary disease. He refers more particularly to the extirpation of the entire bladder for malignant as well as for advanced forms of suppurative diseases. Cases are occasionally met with in which, if it were possible to dispense with the bladder as a receptacle for the urine, its total removal might be safely and advantageously undertaken.

Over four months have now elapsed since completion of the operation.

DISEASES OF THE EAR, NOSE AND THROAT AND EXTERNAL CAVITIES. By Seth Scott Bishop, M.D., LL.D.  
Philadelphia: The F. A. Davis Publishing Company. 1897.

In the preface of this book Dr. Bishop tells us he has written it because of frequent requests received from medical students that he should prepare such a work, and he has also designed it for the purpose of aiding the practitioner of medicine after his graduation. As may be imagined from its title, the book attempts to be quite exhaustive. The first part is devoted to a consideration of the anatomy of the parts which are to be treated, and then follows a somewhat lengthy consideration of the various forms of compressed air apparatus, vaporizers, and inhalers which are used commonly in the treatment of dis-

eases of the upper air passages. An examination of the text and the cuts shows that he quotes freely from contemporaneous writers, notably Sajous, Burnett, Tuttle, and Ingals.

As in most of the books issued by The F. A. Davis Publishing Company, numerous good illustrations will be found all through this volume, the most notable of which, perhaps, are the colored plates made by Burk & McFetridge of Philadelphia, which decorate so usefully the well known volume upon *Diseases of the Nose and Throat* by Dr. Charles E. Sajous.

The very large number of illustrations which are used for the elucidation of the text is shown by the fact that there are no less than 168 in this volume. As the title would indicate, the book begins with the consideration of *Diseases of the Ear*, then passes on to the consideration of *Diseases of the Nose*, and finally considers the subject of *Diseases of the Throat*. Some of the illustrations, as for example those on page 13, do not seem to us of any particular value, as they simply illustrate the arrangement of a physician's office in which he devotes himself to the treatment of the diseases with which this book deals.

Considering the extraordinary growth of the three specialties which are embodied in this volume, we can congratulate the author upon having produced a most successful condensed view of the treatment of affections of the head. In the article on the serum treatment of diphtheria Dr. Bishop does not speak as if he had used it, and a large part of the text concerning this subject is in quotation marks and taken from other writers.

**THE MENOPAUSE.** By Andrew F. Currier, B.A., M.D.  
New York: D. Appleton & Co., 1897.

This is a small octavo monograph on the subject of the climacteric, which extends over 281 pages and to which is added an index of authors and a general index of subjects.

As with all the books which are issued by this firm, it is a good specimen of book-making. When we come to the consideration of the volume itself we find that it deals in an interesting way with the changes which are supposed to take place in the human female who has passed middle life. The endeavor of the author has been to show the exact limitations of this physiological process, and he has also endeavored to prove that the development of the menopause does not render the woman peculiarly susceptible to certain diseases, especially cancer of the womb and

breast. With these objects in view he has embodied the results of a large amount of collateral reading and his own personal experience. Several of the chapters are provided with copious bibliographies, and a large amount of statistical information is given in regard to both human beings and the lower animals. The influence of great fertility upon the early development of the menopause, of prostitution, of gastro-intestinal disturbances, and of various other factors is also carefully considered. The book is exactly what it professes to be—a careful summary of our knowledge in regard to this important subject—and Dr. Currier from his very considerable experience is well qualified to produce such a monograph.

**THE LIVER OF DYSPEPTICS, AND PARTICULARLY THE CIRRHOSIS PRODUCED BY AUTOINTOXICATION OF GASTRO-INTESTINAL ORIGIN.** By Dr. Emile Boix.  
Authorized Translation by Paul Richard Brown, M.D., U. S. Army.

New York: G. P. Putnam's Sons, 1897.

It is evident from the title of this book that it deals with that interesting theme "autointoxication," a subject which has engaged the attention of French clinicians for several years and to such an extent as to lead them at times, we fear, to reach conclusions which only great enthusiasm can justify. Clever and enticing as the hypothesis of auto-intoxication may be, we often find in practical medicine that the theory scarcely holds good. When it comes to ascribing hepatic cirrhosis to this cause we think it is carrying the matter a little beyond the bounds of likelihood.

The first chapter deals with the general consideration of the subject, and the second with the poisons of the alimentary canal, while the third discusses the conditions which favor the production of these poisons. The second part of the book is devoted to the liver of dyspeptics, the liver and its poisons, and then in the succeeding chapters the author devotes himself to the proving of his thesis by discussing what he calls dyspeptic cirrhosis and its pathological anatomy. The last part of the book deals with a summary of the experimental work which has been done in the line of producing cirrhosis, then with the author's own studies, and ends with a recapitulation of the subject. The object of the author all through his essay is to prove the existence of a cirrhotic change in the liver peculiar to what he calls dyspepsia. He also believes that butyric acid and lactic, valerianic, and especially acetic acid, are

formed in the intestine, and that these acids have a peculiar power of acting as sclerogenic agents on the hepatic cells. The therapeutic deduction from the whole research is found in a single line, the last in the book. It is that calomel is the best remedy, in the dose of one centigramme.

**SYSTEM OF DISEASES OF THE EYE.** By American, British, Dutch, French, German, and Spanish Authors. Edited by William F. Norris, A.M., M.D., and Charles A. Oliver, A.M., M.D. Volume II. Copiously illustrated.

Philadelphia: J. B. Lippincott Co., 1897.

We have already spoken in terms of high praise of the first volume of this System, which appeared during the past winter. The present volume contains articles written by fifteen contributors, one assistant contributor, and three translators, and deals with the important subjects of the examination of the eye, school hygiene, statistics of blindness, and antisepsis.

The opening article is on the Methods of Determining the Acuity of Vision, by Herman Snellen of Utrecht, Holland, his article being translated by the well known Scotch ophthalmologist, Mr. Berry. It is hardly necessary to point out that an article on this important subject by one who has taken so much interest in it is of practical utility and worthy of the System to which it is contributed. The same author also contributes the succeeding chapter on Mydriatics and Myotics, and we feel a little disappointed in its brevity, for we think that this important subject might have been extended beyond the short space of fifteen or sixteen pages. It does not seem to us that the various studies which have been made as to the manner in which mydriatics produce their effects have received sufficient attention in this paper.

The third chapter is upon Lateral Illumination and the magnifying instruments employed in combination with it, and is written by Laqueur of Strasburg, the translation being made by Dr. Friedenwald of Baltimore. This chapter extends from page 47 to page 61, and is followed by one upon the Ophthalmoscope and Art of Ophthalmoscopy, by Dr. George M. Gould of Philadelphia, which extends over twenty-four pages. Here, again, we are surprised at the brevity of the discussion of such an important subject in so large a System. Very properly the chapter upon Skiascopy (the Shadow-Test, Retinoscopy) and its practical application has been given to Dr. Edward Jackson of Philadelphia, whose work upon this subject is well known to the profes-

sion; while Adolph Javal, Jr., discusses Ophthalmometry and its Clinical Applications very appropriately.

Dennett of New York contributes a chapter upon Prisms and Prismometry, and Stevens of the same city, so well known as an expert on the subject of the balance of the ocular muscles, writes upon this topic.

The Detection of Color Blindness is discussed by Dr. William Thomson, assisted by Dr. Carl Weiland.

The chapter upon Blindness: its Frequency, Cause, and Prevention, by Dr. I. Minis Hays, of Philadelphia, is one which is strongly fortified by valuable statistics.

From what has been said so far it must be evident to our readers that the editors of this System have been peculiarly fortunate in obtaining writers of high authority upon the various subjects. Almost every contributor is recognized as a law-giver in the study of the subject of which he writes, and those who have edited a System know how difficult it is to obtain the very best authors for special subjects.

The volume ends with a very complete index and list of contributors to the System, and a schedule of the various articles which will make up the complete system. Both editors and publishers deserve great credit for placing before the profession a most valuable encyclopedia, and we trust that their efforts will be fully appreciated.

**SYSTEM OF SURGERY.** Edited by Frederic S. Dennis, M.D., assisted by John S. Billings, M.D. Volume III. Illustrated.

Philadelphia: Lea Brothers & Company.

The writer of this notice has but to repeat the good words given the two volumes of this System previously reviewed in the THERAPEUTIC GAZETTE. The following subjects are discussed: Surgery of the Larynx, Tongue, Jaws, Teeth, Salivary Glands, Neck and Chest; Diseases and Surgery of the Eye and Ear; Surgical Diseases of the Skin; Surgery of the Genito-Urinary System; and Syphilis.

The name of its editor, Frederic S. Dennis, and of such contributors as George E. de Schweinitz, J. William White, Robert W. Taylor, William A. Hardaway, Louis McLane Tiffany, and H. H. Mudd, will serve as a hall-mark to the busy practitioner and careful student, that in selecting this work he is obtaining the latest information on the subjects discussed and many practical methods embodied in the most concise language.

The book contains 919 pages, including an adequate index. The publishers are to be

congratulated on the book-making part of the work; the type is clear and the text elucidated with many illustrations and a number of colored plates.

We bespeak for this volume a continuation of the success attending the appearance of its predecessors. \*

### LONDON LETTER.

BY RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P.

The past month has been devoted wholly and entirely in one or other form to Jubilee celebrations. The medical societies have all closed their doors for the summer, and the current medical journals are sufficient evidence of the general stagnation of matters medical. Following the example of the *Practitioner*, to which we alluded in our last letter, most of them have blossomed out into a Jubilee number. The occasion is most certainly a favorable one for retrospection, as everything is pervaded with a supersaturated holiday atmosphere, and nothing is a-doing. Even about the hospitals there is a sense of listlessness; many beds are empty, and the out-patient departments are sparsely attended, and all because for the moment the public has something that interests it more than its own ailments. With only a month remaining until the hospitals begin their annual closing for cleaning and repairs, we hardly look forward to a great awakening until the commencement of the winter session. Only the children's hospitals are busy, as the extent and intensity of any great national rejoicing may usually be expressed in terms of infantile diarrhea. London is now slowly emerging from its casing of wood, and the din of hammer and saw and axe is silent; there are still only too obvious signs of an overflow population, but with the return of visitors and the approaching end of the London season, the streets are daily becoming more passable. Only a week since "All board and no lodging" was a terse but truthful description of existing conditions, with every house along the route hidden in hoarding and tenanted two deep from cellar to garret.

The distribution of medical honors will be generally approved by the profession both by reason of the fitness of the recipients and the numerical limitation. None is more \*thoroughly deserved and none will be more

generally welcomed than the knighthood bestowed on Dr. W. R. Gowers, who has won so high a reputation in this country and on the Continent for his investigations of diseases of the nervous system; over and above this there is probably not in London a more fascinating teacher, both at the bedside and on paper. The medical honors are fitting recognition of the enormous advances that have been made in all departments of the healing art during her Majesty's reign. Her Majesty looked wonderfully well, and bore the heat and toil of the day without any undue fatigue, and that this should be possible after seventy-eight summers, if not a tribute to the skill of modern medicine, is valuable testimony to the benefits of fresh air, in which her Majesty has so much faith—an example that might be followed to advantage by more of her subjects. In spite of the enormous crowds that witnessed the procession on Jubilee Day, the casualty list was exceedingly trivial, and but little work was forthcoming for the extensive ambulance service provided at stations all along the six miles of route. Besides the ambulatory contingent in the crowd, armed with stretchers and sal volatile, temporary hospitals afforded possible accommodation for some hundreds of patients. Happily these were not requisitioned at all. Such cases as required attention were mainly attacks of faintness, and these in the majority of instances could not be attributed to the crowd so much as to the self-inflicted exhaustion which inevitably results from commencing a holiday in summer at sunrise, more especially after a night made hideous by the din of preparations for the morrow. As a fact the streets were never at any period of the ceremony densely crowded, as with the persistent fall in prices the large majority of sightseers had provided themselves with seats in the course of the last few days. Syndicates and dealers in seats will hardly join in the general rejoicing, as in this undertaking almost as much money was lost as gained. And no one has a word of pity for them, as this state of affairs was entirely brought about by their rapacity in the early days of seat selling. Very many who would gladly have taken a seat at a reasonable figure were unable to do so at the figure demanded at first, and made their plans accordingly to spend the day in peace and quiet away from the metropolis. The knowing ones held their purse strings until the "slump" set in, and during the procession people were seated side by side

who had paid as differently as fifteen guineas and half-a-guinea for their seats, and only because the latter had waited to the last moment. The absence of a single casualty in connection with newly-erected stands and house accommodation testifies to the thoroughness with which the official inspection was carried out. This is amazing to anyone who saw the rickety floors on which hundreds of sightseers were accommodated on seats raised from the anterior inferior to the posterior superior angles of rooms, so that the uppermost ousted the flies from their privileged habitat on the ceilings. Zaccheus is still with us, and falls from trees were accountable for one or two serious accidents, which otherwise were chiefly conspicuous by their absence. Enquiry at the hospitals along the route showed that very few casualties, trivial or otherwise, were treated at these institutions. The weather was certainly conducive to this end, as the morning opened cool and cloudy, and it was only just as her Majesty left Buckingham Palace that the sun shone out brilliantly. Another factor was the provision of abundant water all along the route by standpipes fitted with drinking-cups. Still it would be absurd to suppose that the British public celebrated their holiday exclusively on that innocuous beverage—even in this age of enlightenment of the masses there still lurks an ill-founded prejudice to its adoption both for internal and external application. However, there was a quite remarkable absence of drunkenness both during the day and at night, and nothing in Jubilee Day can be a more sincere subject of rejoicing than the gradual and evident growth of temperance among the working classes. It represents the clearing of a cloud that has overhung the domestic happiness of the nation, and the casting out of a canker that has blighted the nation's supreme prosperity. There are rumors of legislation dealing with habitual drunkards, but we fear that it is not in the near future. While our rulers are largely publicans, we cannot look for severe disciplinary treatment for bibulous sinners.

The Prince of Wales Hospital Fund has hung fire: every one's purse has been heavily taxed in one or other way for the Jubilee celebrations. It was anticipated that the total would be swelled by one or more large individual benefactions; but such of these as have been forthcoming have been devoted to other objects. Sir Blundell Maple has given the magnificent sum of £120,000 for the re-

building of University College Hospital in the most modern style of hospital construction, while Mr. Lipton's £25,000 has already found its way in the form of beef and plum-pudding into the stomachs of the Princess of Wales' poor. Then again the charitable public would have liked some clearer assurance of the ways and means of distributing the sum collected. Every one is agreed that such matters as these should be the duty of a Central Hospital Board, but there is great diversity of feeling as to the constitution of that Board. The sum already collected will provide an annual income of something like twenty-five thousand pounds a year, instead of the hundred or hundred and fifty that was hoped for. We do not now look for any very substantial addition to this sum, although no doubt a considerable sum will be derived from the sale of the Prince of Wales Hospital Stamp, and of the shilling illustrated Jubilee programme that was sold all along the route on the day of the procession. We cannot at present form any estimate of the extent to which this special appeal will interfere with the regular income of the hospitals. Hospital secretaries have already realized that in this respect the original intention of the fund, to appeal to a class other than the regular subscribers, has not been maintained.

We have little to bring to your notice in current medical literature: Sir Richard Quain read an interesting paper to the Royal Society on the "Mechanism by which the First Sound of the Heart is Produced." The author ruthlessly upsets the theories on which the present generation was nurtured. Neither the closure of the auriculo-ventricular valves nor the muscular contraction of the ventricular walls is a factor in the production of the first sound. The tension of the auriculo-ventricular valves is put out of court by the fact that the first sound is distinctly present in reptiles, in which the auriculo-ventricular valves exist only in a rudimentary form. Thus in the python, which was employed to demonstrate the fact, the valves are merely muscular flaps, destitute of *musculi papillares* and *chordæ tendineæ*, and of any mechanism for producing valvular tension. Clinically, too, this is consonant with the fact that in the presence of a loud systolic murmur of mitral regurgitation at the apex, we frequently hear a normal first sound at the base of the heart. Again the muscular contraction of the walls of the heart during systole cannot be the source of the first sound of the heart. In the first place it is totally different in charac-

ter from the gentle purring sound produced by the contraction of large muscles in other parts of the body. On this point the experimental results of Quain stand in absolute contradiction to those obtained by Ludwig, Krehl, and Kasem-Beck. He finds that although the heart continues to beat, the first sound is absent whenever the circulation in the heart is stopped by clamping the large veins that bring blood into the heart; this also is the case with the turtle's heart after removal from the body. The author turns to his own use another class of experiments which have been employed to show that the contraction of the muscle is a source of the sound. Hürthle and Einthosen have shown by graphic methods that the first sound begins with the very beginning of the systole, before the ventricle has got power to open the valves; and this brings us to the constructive portion of Sir Richard Quain's communication. In this he endeavors to show that the first sound of the heart is produced by the impact of the blood driven by the action of the muscular walls of the ventricles against the block produced by the columns of blood in the pulmonary artery and aorta, which press upon the semilunar valves. "Sound is a phenomenon resulting from resisted motion." Within the left ventricle the motion of the blood stream is in three spiral columns, which are concentrated into one similar stream before reaching the orifice of the aorta: by this "rifle" mechanism a maximum precision and velocity is imparted to the moving columns of blood. The resistance to this current of blood from the ventricle is represented by the weight of the column of blood resting on the aortic valves. Normally the ratio of the driving power to the resistance is as four to three. Sir Richard Quain submits that the first sound of the heart is the product of these two factors, and that it is produced at the aortic valves, although owing to the anatomical relationships of the heart the sound is best heard at the apex. In conclusion he describes a simple experimental mechanism by which sounds resembling the first (and second) sound of the heart can be produced artificially in accordance with this explanatory theory.

At the Royal Medical and Chirurgical Society Dr. Dickinson read a paper on "Musical Mitral Murmurs in Connection with Aortic Stenosis." The murmur might be due either to actual disease or to relative incompetence of the mitral valve, but in all probability the peculiar squeaking or even musical char-

acter of the murmur was due to the force under which the mitral regurgitation was produced, perhaps reinforced by the narrowness of the orifice of escape.

---

### PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

---

It is not necessary to leave France in order to see strange customs, though usually it is only by chance that one learns of the existence of the curiosities in the social life of the various regions of this country.

Recently a tourist discovered not far from Paris (70 kilometers, less than 50 miles away) some individuals whose mode of life was so singular that it was thought worth while not only to give a description of them in the *Revue de l'Ecole d'Anthropologie*, but even to make an excursion to their dwelling-place in order to see them.

In the valley of the river Eure, in the department of the same name, and to the west of Paris, there are to be found, about one kilometer from the village of Ezy, a series of caverns dug in a hillside overlooking the river. These caverns are in three rows, one above the other, and give out onto platforms of earth built in front of them. They probably date back to the middle ages. Nearby are to be seen the ruins of a few houses.

About eighty persons, more or less, inhabit the caves. They are men, women, and children. They live in the greatest degradation, by begging or petty thieving, and carry on no occupation of any kind. Their clothing is filthy, and in many cases hardly merits that name. Children almost grown up go nearly naked.

Absolutely no furniture is to be seen in the caves. For beds dried leaves are collected and kept in a framework of wood; in some cases even the framework of wood is absent. Old sardine boxes and tins of various kinds, picked up in the roads, serve for kitchen utensils. A well at the foot of the slope supplies them with water.

Among them are several families with from four to five children each. These families have been formed in the place itself, and in some cases between individuals who themselves had grown up in the caverns. It is needless to say that any formality as to marriage, as well as taxes, schooling for the children, etc., are unknown to them. It may be added that so low is the condition of these people that the ground before the caves

which they occupy is covered with their excrement.

A well known philanthropist, Mr. Frédéric Passy, who for some time resided in the neighborhood, endeavored to ameliorate their condition, but with little success.

A case which interested the Academy of Medicine not long ago was the following: A patient died of hydrophobia, and the following day the autopsy-room porter, while removing the pancreas, pricked his finger. Two days later he began the accustomed treatment at the Pasteur Institute, which was continued for eight days, when he felt tired and uneasy, with some lumbar pain. On the following day the temperature was 38° C. Hyperesthesia and a sensation of heaviness in the legs were noted. Later on paresis and formication in the legs, with girdle-pains, developed, and on the third day after the onset of the symptoms urinary disturbances were manifest. Complete paraplegia both as to movement and sensation were present on the fourth day; on the fifth day giddiness and vomiting; on the sixth day the arms were affected and the head could with difficulty be moved. The heart-beats were 140 in number, and breathing was difficult. Notwithstanding these symptoms, it was thought advisable to carry out the usual antirabic treatment.

On the seventh day some improvement in the symptoms was noted; the arms were better, and the legs were no longer without sensation. Improvement continued, and on the twenty-fifth day the patient was able to leave for the country.

At first it had been thought that the patient was suffering from the paralytic form of rabies. This idea, however, was finally decided to be inexact, and the physician who treated the patient considered the case to be one of acute ascending myelitis of toxic origin, due to the injections of spinal-cord preparations acting upon an individual who by his occupation was necessarily chronically infected, and consequently apt to be easily affected by the toxins found in the emulsions used.

In the discussion that followed Dr. Roux stated that he could not agree with the above conclusions. If the symptoms noted had been due to toxins contained in the spinal cord used for the injections, the continuance of these latter would have aggravated the case. This, however, did not occur.

Two similar cases had been observed, according to Dr. Roux, at the Pasteur Institute,

both of which had rapidly recovered, and these two cases were the only ones known out of 19,000 cases treated. Dr. Roux thought that if 19,000 persons having either been vaccinated or having taken sea-baths were examined, it would be more than likely that one or two such cases might be found among them. A greater argument was that almost any amount of the emulsion used during the first few days, when the symptoms came on, could be injected into animals without giving rise to any disturbance.

Dr. Laveran had seen a somewhat similar case in a military hospital, ending in recovery, and had come to the conclusion that it was due to an abortive form of rabies, and not to the effect of the injection.

Dr. Brouardel said he considered the case was very likely one of infectious myelitis, but not due to the injections made during the treatment. Such attacks of myelitis were not in reality so very uncommon. It might indeed be a case of paralytic rabies, cured in fact by the continuance of the treatment begun. This would then be a point in favor of the antirabic treatment.

In 1895 M. Dastre, of Paris, while studying the phenomena of coagulation in blood, discovered that the injection of gelatin into the veins of a dog accelerated the process.

Dr. Lancereaux presented recently to the Academy of Medicine a report of a case in which he had endeavored to treat an internal aneurism by the above method. The patient was a male adult, aged forty-six years. For two years he had been suffering from an aneurism of the first portion of the arch of the aorta, which seemed to be in great part due to the efforts required in his occupation of tending a certain piece of machinery, as the first symptoms appeared six months after the patient had taken up the task. These symptoms consisted in neuralgic pains in the upper intercostal nerves on the right, extending into the inner side of the arm. Six months later attacks of angina pectoris appeared, and finally a small tumor appeared on the thorax and gradually increased.

When Dr. Lancereaux first saw the patient the upper and anterior portion of the thorax presented a tumor of the size of a child's head, measuring 12 centimeters vertically and 12½ centimeters transversely. The second, third, and fourth cartilages, the greater part of the sternum, and portions of the second, third, and fourth ribs had disappeared.

The aneurism increased gradually in size, and here and there on its surface were to be

seen dark-colored smaller swellings where the blood was directly brought into contact with the skin.

Inasmuch as the case appeared to be so dangerous, it was decided to inject into the left buttock fifty cubic centimeters of a sterilized one-per-cent. solution of gelatin, at the temperature of 37° C. This caused the temperature of the patient to go up to 38° C., but on the following day the general condition was again normal, and the tumor had become harder. During the next few days the tumor diminished somewhat in size, and the pain which had been felt by the patient completely disappeared. Recurrence of the pains and of the other symptoms were followed by the same results as at first on an injection of 150 cubic centimeters being made. Twelve other injections were made, from two to five days apart. The final result was that the tumor had considerably diminished in size, was firm to the touch, and though pulsation could still be felt in it, it was no longer expansive in character, but seemed rather to be due to the impulse given by the aorta beneath. The patient felt so well that he insisted on leaving the hospital.

A young poet who for some time had been accustomed to use both hashish and morphine, recently committed suicide by means of an overdose of the latter drug. By his will he left the greater part of his fortune, amounting to one hundred and twenty thousand dollars, to his mistress, and one thousand dollars to a member of the legal profession. If, however, his will were attacked by any members of his family on account of supposed undue influence, the entire amount was to go to the latter legatee. As it happened the brother-in-law of the poet endeavored to have the will annulled, not on account of undue influence, but because of the well known abuse of morphine which the deceased had suffered from. The court decided that inasmuch as the abuse of morphine could not be considered as in any way doing away with the culpability of the individual in a criminal case, it could not be regarded as diminishing the responsibility of the individual in a civil cause.

This decision is opposed to the decision given some years ago in a case tried in Hartford, Connecticut, in which a will was annulled on account of the abuse of morphine and alcohol.

France is one of the few countries in which the positions of physicians and surgeons to the hospitals and of assistant professors at the

faculties of medicine are filled by competitive examination. Of late years complaints have arisen of favoritism having been shown in the choice made. At the examination for hospital physician which took place this spring, one of the judges, Dr. Variot, published an article in a medical paper, in which he stated that he could see no reason why any such examination should be held, as out of seventy-five candidates the three whom public opinion, previous to the examination, had designated as being especially favored by members of the jury were nominated. This article caused considerable commotion, so much so that one of the medical societies of Paris, which was formed by the reunion of the hospital physicians, held a secret session for the purpose of judging Dr. Variot's conduct in publishing the article.

A still greater excitement has been caused by the resignation of a member of another jury more recently formed, on account, as he said, of the jury having given the highest possible mark to a candidate who had made a mistake in diagnosis, but who was especially protected by other members of the jury.

One of the most illustrious men of French medicine, Duchenne, has but just now had a monument erected to his memory at the Salpêtrière Hospital. The monument consists in a tablet, the upper part of which forms a medallion in which is placed a profile view of the head of Duchenne. Below this medallion is a bas-relief representing Duchenne testing by means of electricity the muscular system of a patient. Representatives of the Faculty of Medicine of Paris and of the various learned societies, as well as of the Government, were present at the inauguration.

Duchenne is so well known that it is hardly worth while to mention his works on "The Application of Localized Electricity to Physiology," etc., and "The Mechanism of Human Physiology." It is chiefly in connection with two affections—locomotor ataxia and progressive muscular atrophy—that his name is connected. Duchenne, who was always called of Boulogne on account of having practised in that city previous to his arrival in Paris, was never connected in any way with the Faculty of Medicine; in fact, during his life he was looked upon by most of those with whom he came into contact in the hospitals as an intruder, if not a quack. Trousseau, it is true, recognized the value of his discoveries.

### THE RAPIDITY OF ABSORPTION AND ELIMINATION OF SOME COMMONLY EMPLOYED DRUGS AS A GUIDE TO THEIR ADMINISTRATION.

By H. A. HARE, M.D.,

Professor of Therapeutics in the Jefferson Medical College  
of Philadelphia.

The knowledge of the effects of drugs upon the human or animal organism is a *sine qua non* of successful therapeutics of a rational

type, and its importance is so great that any argument in support of a closer study of the action of remedies is useless. Too often, however, we study the effect of the drug upon the different organs upon which we wish it to exercise a particular influence and ignore its influence upon the organs of absorption and elimination, although the speed and manner of absorption and elimination should govern our dosage, as to size and frequency. The direct influence of the remedy as it passes through the absorbing organs and those of elimination may be great.

A study of modern medical literature re-

veals a distressing lack of attention to these points, and we find careful practitioners ordering drugs which are slowly eliminated very frequently in twenty-four hours, and drugs which are rapidly eliminated very seldom in twenty-four hours; with the result in the latter instance of practising what an eminent therapist has called "kangaroo therapeutics," viz., a great effect of short duration at long intervals. Thus to give dilute hydrocyanic acid, three times a day for the relief of cough will produce a sedative influence of a powerful character, which will last at the most but a few minutes and leave the patient unmedicated for several hours; and the use of ammonia as a stimulant in a similar manner is equally futile. On the other hand the frequent administration of digitalis or the bromides is unnecessary, for these drugs are so slowly absorbed that the system receives a gradual dose, so to speak, and they are so slowly eliminated that if the doses are frequent the drugs simply accumulate in the body and produce an excessive effect.

All drugs cannot be arbitrarily divided into those which are slowly and those which are rapidly eliminated, but some drugs do lend themselves to such a classification, and some of those which are slow of absorption are slow of elimination. It is because drugs which are slowly eliminated are frequently given too often in twenty-four hours that the so-called "untoward effects" of many of them are developed; and in reality a large number of drugs produce a cumulative effect, although this term is usually applied to the effect of the excessive use of digitalis. The difference in the effect of digitalis when it accumulates is that some change in the position of the patient may bring on the symptoms suddenly, and therefore a greater impression is made on the mind of the physician and perhaps on the body of the patient.

The reliable information that we have as to the absorption and elimination of drugs is by no means as complete as is desirable. No part of pharmacological study is more neglected. In many instances no studies as to the elimination of important remedies have been made. In other cases the drug is so completely destroyed in the body as to prevent any estimation of its presence in the urine, as for example in the drug digitalis; and again in some instances the methods of testing for the substance in the eliminative secretion cannot be relied upon. I trust at some future time to present original studies

on this point, but at present I shall only gather together for your consideration the facts already scattered through some of the literature.

Of the mineral drugs which are rapidly absorbed and eliminated we find the following:

The iodide of potassium is absorbed and eliminated so rapidly when taken by the empty stomach, even in so small a dose as three grains, that it appears in the saliva and urine in from ten to twenty-five minutes, usually in about fifteen minutes. It does not tend to accumulate in the system to any great extent. Its rapidity of total elimination is apparently not so great as its speed of total absorption, for though it soon disappears from the stomach it appears in the saliva for about thirty-six hours afterwards. These results have been reached by a number of observers, but the figures given here are my own. Soullier asserts that the iodine appears in the urine and saliva in so short a time as five minutes, and this statement is endorsed by Desprez (*De l'Elimination de l'Iodine de Potassium par les Urine*, 1884). Doux states that thirteen minutes usually elapses before elimination begins.

Not only is the drug speedily found in the saliva, but the largest part of the dose taken escapes within twenty-four hours. About eighty per cent. escapes in this brief period, but on the other hand the drug remains in small amounts much longer than this. Ehlers (*Annals de Dermatolog. et Syphilog.*, 1890) states that this residual quantity is slowly eliminated over a period of five days. John Marshall found that 265 grains a day could be recovered from the urine of a patient taking 360 grains a day. There are several reasons why this result is reached. First, the amount eliminated by the urine does not represent that eliminated by the saliva, and probably there is also an elimination by the bowel, so that an amount considerably over that found by Marshall really escapes from the body if the patient defecates or expectorates. On the other hand, one of the reasons why a certain portion remains uneliminated is that being eliminated in the saliva it is swallowed and reabsorbed. Then, too, it is probable that some of the iodine unites with the albumen of the tissues, forming slowly soluble albuminoid compounds of iodine, and so this quantity is delayed in the body.

It is evident, therefore, that in the use of iodide of potassium we should give it freely and frequently at first until the residual

amount has reached its limit, when smaller doses may be given and given less frequently for the purpose of maintaining the iodine influence. That is to say, the drug should be given up to the point of tolerance, whatever that may be, and then a smaller dose will be sufficient to maintain its influence by replacing the albuminoid compounds as they are slowly eliminated. On the other hand, if the iodide is being given for the purpose of eliminating some poison, as lead for example, here the dose cannot be greatly decreased because in addition to the ordinary quantity eliminated a proportion is passed out as a double soluble iodide of lead. This theoretical objection seems to find support in the fact that after the syphilographer reaches the full effect of the drug he often cuts the dose down to what he calls the "tonic dose," and so maintains the constant alterative effect without disordering the functions of the body. If he does not do this the drug accumulates and causes chronic iodine cachexia, a state which it is important to avoid in grave disease like syphilis, which depends for its relief so largely on the development of great vitality in the patient.

It is interesting to note in this connection that when we give iodide of potassium the iodine unites with the sodium in the blood and is so eliminated, whereas the potassium itself is more slowly eliminated; and as it has a depressant effect on the vital functions it cannot be ignored. This is illustrated in regard to another iodine compound by an experiment of Issersohn, who gave iodide of lithium hypodermically and recovered all the iodine in the first twenty-four hours, but not all the lithium for forty hours. The facts in regard to the iodide of sodium are such as to strongly commend it as a substitute in medicine for the potassium salt. I have already shown in one paper, as have many others before me, that potassium is a powerful depressant, while sodium is not. Again, when iodide of potassium is taken internally it is decomposed and iodide of sodium is found. The sodium salt, therefore, possesses great advantages, as it contains practically as much iodine as the potassium salt.

Iodine itself is properly used less than the iodides because it is irritant and more slowly absorbed, and seems to produce more irritation in its elimination than iodine derived from the salts named.

Bromide of potassium has been studied very thoroughly as to its absorption and elimination. It is absorbed rapidly and exceed-

ingly slowly eliminated. Thus Rabuteau asserts that five minutes after it is taken it begins to be eliminated, and in ten minutes its presence is most manifest. Amory found one-half of the drug eliminated in twenty-four hours and one-third in the next twenty-four; but the important fact for us to remember, from a therapeutic point of view, is that the balance of this drug is perhaps more slowly eliminated than any of the common remedies, for Bill (*American Journal of the Medical Sciences*, July, 1868) found it in the urine two weeks after the drug had been stopped, and Rabuteau found it one month after. The same rule which was stated as governing the use of the iodides holds here, namely, that after the drug is once manifesting its full effect smaller doses will maintain its effects, and this is the method in which those neurologists who use it most generally employ it, namely, full doses for one week and then small doses only large enough to preserve the effects. Probably few general practitioners follow this custom.

It is manifest, therefore, from what I have said that the administration of either iodides or bromides in frequent small doses possesses no advantages and is apt to disorder the digestion and overload the organism with the drug. They should be given twice or thrice a day in full dose rather than frequently in small doses.

The rapidity of absorption and elimination of mercury depends to a very great extent on the variety of it which is given. The drug in some forms is so soluble, in others so insoluble, that very great delay in its elimination must often ensue because it is slowly absorbed. It will be futile in this brief paper to discuss the form in which mercury is absorbed. It is usually taught in France that the theory of Miahl is correct; this is that the mercurial preparations are transformed in the stomach and intestine into the bichloride, which in turn unites with the sodium chloride in the blood and circulates as a double chloride of mercury and sodium. In Germany it is taught that it forms an albuminate of mercury and so circulates (Henoch's theory), or that it forms a chloro-albuminate (Voit's theory). All theories as to the form of its absorption are open to grave criticism. As to the elimination of mercury, it is known to escape by every avenue of exit from the body—the urine, feces, sweat, tears, milk, and saliva. After a single dose the drug begins to be eliminated in about two hours according to Byasson, and is entirely gotten rid of

in twenty-four hours. If, however, the doses are persisted in it gradually accumulates in the body and is so slowly eliminated as to remain for almost indefinite periods of time, and is found deposited in all the organs. In other words, the doses of mercury ordinarily given are always large enough to produce cumulative effects. Thus while Balzer and Klumpke agree with Byasson as to the rapidity of elimination of a single dose, they find from an experimental study that the amount of mercury which can be eliminated by the kidneys for many weeks when the body is saturated with the drug is only one-sixteenth of a grain a day. It is evident therefore that after a full mercurial effect is produced it is well to decrease, as do most syphilographers, the dose of mercury and only give enough to maintain the effect. It is also evident that their plan of using iodide of potassium every now and again to aid in the elimination of the residual mercury is advisable.

Antipyrin is rapidly absorbed from the stomach in a space of from fifteen minutes to half an hour, and begins to appear in the urine at this time; but Reihlen asserts that its elimination continues for from thirty-three to fifty-six hours after the last dose. It therefore should not be given in too frequent doses. In regard to acetanilid we have the assertion of Kumagawa that it is absorbed in half an hour and eliminated completely in twenty-four hours, so that it is not as prolonged in its effects as is antipyrin.

Atropine and belladonna are, on the other hand, absorbed with extraordinary rapidity and equally rapidly eliminated in the urine. Harley asserts that elimination is complete in two hours. This drug may therefore be wisely given frequently. Aconite is also rapidly absorbed and destroyed by oxidation, so that its effects do not last for any length of time.

Arsenious acid is absorbed fairly rapidly, but eliminated very slowly indeed, chiefly by the kidneys and the sweat. It begins only after the lapse of fourteen hours and continues for sixty hours, and it is thought by some that the development of an arsenical rash is an indication that elimination through the skin is beginning. This drug ought therefore to be given at long intervals rather than in many doses each day.

I have called attention to these facts in regard to the absorption and elimination of drugs because I do not think that enough attention is given to this important subject when drugs are given.

## *TWO HUNDRED CASES OF SPEECH DEFECTS AT THE PHILADELPHIA POLYCLINIC HOSPITAL.\**

BY G. HUDSON MAKUEN, M.D.,

Professor of Defects of Speech in the Philadelphia Polyclinic and College for Graduates in Medicine; Laryngologist to St. Mary's Hospital and to the Frederick Douglas Memorial Hospital, Philadelphia, Pa.

It has long been a source of surprise to me that the function of speech, which plays such an important part in the history of our civilization and in the physical and mental development of man, should receive so little attention at the hands of the medical profession. In comparison with the advancement which we have made in our studies of the other leading faculties of the human organism, we are many years behind the times with the faculty of speech.

We no longer look to the enterprising optician to correct our errors of refraction, but we still depend upon his twin brother—the quack stutter-doctor with his tricks and secret mechanical contrivances—to correct our defects of speech. This is a fact greatly to our discredit, for there are no sufferers who require the careful, conscientious treatment of the skilled physician more than those who think with a stammering brain and speak with a stammering tongue. It is with this fact in view, and with the hope of placing the whole subject on a more scientifically workable basis, that I have undertaken its study.

In the somewhat less than a half year that my clinic has been in operation, nearly two hundred cases have presented themselves for treatment. Of these two hundred cases, one hundred and forty were stammerers, and the remaining sixty represented all the other varieties of vocal and speech defects of which I have any knowledge, and one or two varieties which have never been reported.

You will readily see that to do justice to my subject would require more time than I have at my disposal, and so I have concluded to read only that part of my paper which refers to stammering, and to draw some conclusions from my one hundred and forty cases with reference to the nature of the affection, its etiology, and its treatment.

Ninety-five per cent. of my patients were males, and they ranged all the way from six to fifty-three years of age. Thirty-two per cent. are reported to have stammered from

\* Paper read before the Medical Society of the State of Pennsylvania, May 19, 1897.

the very inception of their speech development; fifty-two per cent. began between the ages of three and ten years; two began at eleven years, one at twelve, one at fourteen, and two at fifteen years of age.

About seventeen per cent. claimed some improvement with increasing years, while twenty-five per cent. were getting worse; thirty per cent. had associated with persons similarly afflicted; and thirty-two per cent. had relatives who stammered.

Seventeen per cent. ascribed the origin of their trouble to the voluntary imitation of others; fifteen per cent. to having received a fright; eight per cent. to an injury; and six per cent. to having been ill-used at home.

Whooping-cough, measles, scarlet fever, diphtheria, and smallpox have all figured as supposedly causative factors, although these diseases have not been especially prevalent among them. Consumption had made inroads into the families of twenty-five per cent. of my cases; and this is an interesting fact when we consider that stammering is always accompanied by marked irregularities in the respiratory function.

There was a family history of insanity in three of my cases; and no imbecility or idiocy. The usual reply to my question, "Bright or dull?" was "Very bright;" but this was true only in certain lines. Some of the faculties appear abnormally acute, while others are below the average. This is especially true of those who have stammered for a long time. Not only is there an impairment of the mind, but there is a physical impairment as well; and few of them claim to be in good general health. "Weak and nervous" is a favorite expression with them; and many attribute their whole trouble to this condition.

Of special interest to me has been the study of the objective conditions or appearances of these patients. They present a peculiar physiognomy which is almost pathognomonic. Their dejected facial expression is probably due largely to the great mental depression which many of them experience on account of their defect; but the general contour of the head and face is a part of their natural inheritance; and it is certainly suggestive of the degenerate type.

The thoracic development is fairly good in most of these cases, but there is a total lack of voluntary respiratory control. It is by no means uncommon to find one with a well developed chest who is unable to make more than an inch or an inch and a half difference

between the girth of forced expiration and that of forced inspiration.

Now as to the condition of the organs of speech as seen by direct inspection and by means of the rhinoscope and the laryngoscope: First, the tongue. I have had only one case of tongue-tie where it was necessary to clip the frænum; but there were four cases in which the anterior fibers of the genio-hyoglossus muscle were too short, and in which division of these fibers seemed to be indicated in order to give a free motion to the tip of the tongue. My method of doing this operation will be found fully described and illustrated in the *Journal of International Clinics*, vol. i, 7th series, April, 1897. In several cases the tongue was found to be hypertrophied; there was too much of it, and it seemed to be in its own way. I have not thought it necessary to attempt an operation to remedy this condition, but as early as 1841 Dieffenbach removed a wedge-shaped piece by means of a horizontal section at the base of the tongue for the relief of stammering; and the operation might be justifiable where the tongue is very long and thick.

The uvula has presented some interesting anomalies. There were eight bifid uvulas; and there were many cases in which it seemed to turn at right angles upon itself and point horizontally in various directions. In one case the uvula was divided throughout its entire length, and there was a large congenital perforation in the anterior palatal fold. Another case had a long epiglottis which appeared above the base of the tongue, and a portion of which I removed with the electric knife.

Hypertrophied faucial and pharyngeal tonsils and intranasal lesions have been frequently met with, and a general catarrhal condition of the nose and throat is the rule. That this catarrhal condition is due in part, at least, to the unnatural use of the organs of speech we must admit, but its chief causes are undoubtedly intranasal pressure and hypertrophied pharyngeal and faucial tonsils.

Having considered the history of these cases and the objective symptoms and conditions, we are in a position to draw some conclusions as to the nature and cause of stammering.

In the first place, it is an affliction which is confined largely to the male sex—only five per cent. of my cases being female. It comes on during adolescence—the great majority beginning during the early part of the forma-

tive speech period. It is not self-limited and few get well or even improve without special treatment. Heredity is an important factor. Nearly one-third of my cases claimed to have had relatives similarly affected. This would indicate that the tendency or predisposition to stammer is inherited. Imitation, voluntary or involuntary, is a fruitful cause of this trouble. Twenty-four of my cases attributed the origin of their condition to the voluntary imitation of others. A severe nervous shock, the result of fright or injury, is also a common cause. One boy stammered ever since his head was ducked in a tub of cold water; another since he lost an eye in an accident; and another since he was frightened by a large sewer rat. The above observations or facts would seem to prove that stammering is due directly to some disturbance in the cortical speech mechanism, or in the nerve track uniting the cortical with the two peripheral speech mechanisms, viz., the vocal and the oral or articulating mechanism.

Now as to the treatment of stammering. In the first place we must study our case. No two are exactly alike. There are great differences in the varieties and outward manifestations of this affection, as well as in the cause. We must determine, if possible, just where the trouble exists. Is it in the cortical speech mechanism, the vocal mechanism, or in the oral mechanism, or in the nerve tracks which unite these mechanisms? Having reached a conclusion on this point, we must then seek for all possible causes. To be sure we may not find the original cause, for it may have long since ceased to exist and only the stammer remain, but anything which may interfere with the free and harmonious action of the three mechanisms which I have mentioned should be removed. Intranasal lesions, and all oral or pharyngeal and laryngeal irregularities, should be carefully corrected, and the general health of the patient put in the best possible condition. When all this is done the after-treatment is comparatively easy, and the prognosis for a permanent cure is most favorable.

The treatment consists in a systematic course of training which shall be of such a nature as to thoroughly break up certain faulty mental and muscular processes, and to substitute for them certain other natural and physiological processes which shall be governed entirely by an intelligent consciousness.

There is no trick about it. I have no specific to offer. There is no short-cut, easy

method. The treatment for stammering, like all other treatment, must be along the lines of sound physiological and psychological principles. The patient must be taught the exact sounds of the language, and if the speech muscles will not perform their functions properly, they must be trained into right action by the frequent repetition of appropriate exercises. It will not take long to prove to the patient that he can say some things without stammering sometimes; then he must be shown that he can say anything without stammering sometimes; then by frequent repetitions, and by encouragement or suggestion if you please, he must be brought to the point where he knows that he can say anything without stammering at all times and under all circumstances. Then and then only may a cure be said to have been effected.

---

*NEURASTHENIA OR NEURO-STHENIA:  
WHICH? AND AN EFFICIENT  
TREATMENT.*

BY BEVERLEY O. KINNEAR, M.D.

---

The symptoms which denote to the practised eye of the educated physician a case of neurasthenia are essentially those which indicate derangement of the nerve centers, of the cerebro-spinal centers, and also of the sympathetic system. There is a mingling of strength and weakness, an evidence of excessive nervous action, accompanied by constipation, frequently by digestive inactivity, and muscular weakness. There is an active condition of the brain, yet a disability for concentrated mental labor. There are cold extremities, demonstrating a deficient blood-supply and therefore a deficiency in tissue oxygenation and nutrition; but at the same time the motor apparatus of the legs in particular is often seen to be more excitable than in health, as shown by muscular twitchings and jerkings, especially at night. There are attacks of neuralgia, and tendencies to internal congestions.

Many such patients suffer from congestive headaches and sleeplessness; or they may sleep very soundly, but they are always found to waken unrefreshed. They sometimes feel as if they "must escape from their body," so uncomfortable, restless, and excitable are they. They may even have a good appetite, but their food does not appear to nourish them. The respiration is feeble, or shallow; they take cold easily, either in the head, throat, lungs, or muscles,

and are exceedingly sensitive to all temperature changes. They are subject to innumerable uncomfortable sensations—both mental and bodily—and in nine cases out of ten have so concentrated their mentality upon their feelings and sensations that they are a misery to themselves as well as to those who are brought in contact with them.

Hypersensation—both mental and physical—and malnutrition may be said to cover the expression of this disease.

By malnutrition can be understood an *excess* of nutrition, and therefore an excess of function in some parts of the body; as well as a deficiency in the circulation and oxygenation in other parts, illustrating diminished functional power.

It appears to the writer that this is precisely the condition in the so-called neurasthenia.

As this state may be reasonably demonstrated to be due to irregular action of nerve centers—if this be true—then the most efficient treatment for this disease is to restore the normal action and function in the nerve centers, and to supply to all organs and tissues their proper modicum of oxygen.

Let us then (so to speak) dissect the action of the nervous system in the train of symptoms presented, and observe also whether these symptoms be due to increased or to diminished function in central nerve cells.

We must for a moment go back to the causes, or some of the chief ones, which induce this disease. In general terms, any course of action or form of suffering which exhausts the nutritive nerve centers may originate it. Long-continued anxiety, grief, or fear may induce an attack. Unwearied labors of body and mind cause it. Venereal and other excesses are a fruitful source of the condition. The general rush of the age in which we live, in pleasure as well as business, and in the pursuit of knowledge in multitudinous paths, all have a tendency to induce overstrain and exhaustion in the nutritive central nervous system. Heredity is a prominent factor. Accidents, shocks, and the tuberculous diathesis give rise to the disease.

The nerve centers which regulate the nutrition of all organs and all tissues have become so overworked that the balance between these vaso-dilator nerves which expand the arteries, and the sympathetic ganglia—the chief function of which is now acknowledged to be to contract them—has been destroyed. The result is that the sympathetics function abnormally and contract the arteries

in the extremities, causing cool or cold hands, feet, arms, and legs, according to the degree of exhaustion in the vaso-dilator nerve centers.

Here, then, we have neurasthenia in one set of nerve centers, in those which dilate the arterioles, and thus supply oxygen and nutrition to the whole physical frame; while in the sympathetics, or those nerve centers which contract the arteries, we behold a condition of neuro-sthenia or hypernervous action; and it is the writer's opinion that it is this excessive action of the sympathetics which by expelling the blood from the long muscles and extremities not only forces the mass of the blood into the internal organs and cerebro-spinal nervous system, giving rise to all forms of congestions, as well as the general hyperesthesia, but this closed condition of the arterioles in all extreme and superficial regions, particularly in the abdomen and lower body, prevents the access to these parts of their normal supply of oxygen and food.

By the contraction spoken of the blood is forced in excessive quantity into the brain, so that during day and night the gray matter of this most important organ is kept at work, and the result is loss of mental power and weariness, losses of memory, of will power, of concentration, and of consecutive and well balanced thought. An exhausted brain can only signal weak commands, and a poorly nourished muscular system can only reply in a feeble manner. And yet the blood having been driven also in excess into the spinal cord, we have excitement of that organ, as demonstrated in all the forms of exalted sensation, the muscular twitching, and the general restlessness, the whole condition expressing a desire to be up and doing, but a physical and mental incapacity to meet the wishes of the patient. We have at the same time a more or less congested state of the liver, lungs, pancreas, and the whole upper body; therefore an inefficient action of the digestive organs and a partial loss of function in the air cells, so that they are unable to absorb the normal amount of air necessary to the healthful supply of oxygen to the blood, and through the circulation to all tissues.

Goodhart, in his "Common Neuroses," page 40, says: "Children are often brought in for an opinion because they are so thin. They are always eating, yet never do any credit to their victuals, etc. But these children are always twitchy, half-choreic, or excitable, and they are for the most part of a

nervous temperament." Added to the above symptoms we ourselves have noted for many years that such children have invariably cool or cold feet and legs, as well as cold upper extremities, demonstrating thereby a feeble circulation in the muscular apparatus of the greater portion of the body.

Francis X. Dercum, in his text-book on "Nervous Diseases," 1895, declares of neurasthenia: "It is extremely probable that brain, cord, and peripheral nervous system all suffer." This statement from so recent an authority voices our own conclusions without presenting the cause of the suffering referred to.

This we believe to be a powerful neurosthenic action of the sympathetic ganglia, causing a contraction of the general peripheral circulation, depriving all the parts involved of their normal amount of oxygen and nutrition, and giving rise to a general hyperemia of the brain and the spinal cord, internal organs, and upper body; this last condition interfering with nutrition and digestion by the exhaustion of the brain and spinal cord from overstimulation, as well as from the congested state of both excreting and secreting organs, demonstrating *neurasthenia* in the cerebro-spinal system, as opposed to *neuro-sthenia* in the sympathetic ganglia. Therefore it appears to the writer that neurasthenia is a general hyperemia of the brain, spinal cord, and sympathetic ganglia, but an exhaustion of the cerebro-spinal system, in contradistinction to excessive force displayed by the sympathetic ganglia, in the peripheral contraction of the arteries.

Whether this exposition be the true one or not, we all recognize the fact that in neurasthenia we have presented to us patients with a poor circulation, with a tendency to internal congestions, and with a feebly acting brain and muscular system.

If the foregoing be correct, then the main objects to be attained are: to restore a good circulation to the extremities, thus relieving the brain, spinal cord, and internal organs of their congestion, and at the same time to supply every tissue of the body with its normal amount of oxygen.

Before outlining the treatment which we have found most efficient in this disease, let us turn for a few moments to those methods which have been and are adopted to-day.

Rest, seclusion, feeding, and entire restraint from sympathizing friends and relatives was introduced by Dr. Weir Mitchell of Philadelphia. This treatment has had successes,

but also a large number of failures. Massage and electricity have been of service, but in severe cases are not curative. Strychnine has been tried and failed. The various sedatives, such as the bromides, sulphonal, and trional, are temporary quieting agents. Out-of-door exercise within the point of fatigue is beneficial. Change of scene and air to those who can afford it have often worked wonders, but require time and expenditure. Various preparations of iron, but especially the saccharated carbonate, and arsenic also, have been found useful; all of these treatments have been found serviceable and sometimes curative.

Our object is to show that this disease is due to hyperaction in one portion of the nervous apparatus and enfeebled action in the muscular and nutritive nerve centers, the latter being due in the first place to one or more of the originating causes set forth, and secondly to undue stimulation by the forcing of the blood in excess into the already weakened cerebro-spinal system; and also to advocate a treatment which has been proven to be effective in a large number of cases by the writer, and which has seemed to him truly scientific, because it will conquer quickly and safely the conditions of nervous derangement presented in neurasthenia.

How can normal distribution of the blood be accomplished? And how can we supply oxygen to the exhausted nerve centers and to all the organs and tissues of the body? By three methods: The internal administration of oxygen by inhalation; by the intelligent use of cold over the spine; and by those forms of electricity which are known to excite the nutritive processes.

During the past sixteen years we have made more than eight thousand personal applications of cold to the spine, and in a variety of diseases. We know therefore by long-continued clinical observation what results may be obtained by its use. The very first effect of the spinal ice bag is to dilate the arterioles all over the body, if applied from the fourth cervical to the last lumbar vertebra. But in nearly all cases of neurasthenia there is cerebral hyperemia, consequently the bags should only be applied from the fourth dorsal to the last lumbar vertebra. By this method the arteries may be dilated in the lower body, and through this dilatation the excess of blood is drawn from the brain and internal organs, as well as expelled from the spinal centers locally, over which the cold application is placed. We have carried out this

treatment without drugs many times, with excellent and permanent results.

Added to these applications, however, we have found that the proper inhalation of a pure form of oxygen, when properly combined, will ensure a more rapid progress toward recovery than by cold over the spine alone. The formula which has been found most efficacious, and which has been most widely commended by all authorities upon the use of oxygen, is composed of two parts of oxygen, one of nitrous monoxide, and one per cent. of ozone. This is the standard of the London Oxygen Hospital, and it can be obtained fresh from the leading druggists in the country.

It is most important to use oxygen for therapeutical purposes thus combined and prepared, because pure oxygen is so dense in its specific gravity that the arterioles will not absorb it unless combined with a gas of lighter specific gravity; and ozone is required to keep it fresh.

The fact that the capillaries will not absorb pure oxygen alone has been demonstrated by confining small animals in hermetically sealed tanks containing an atmosphere of pure oxygen. They rapidly die of asphyxiation.

Physicians too, as a rule, are not aware that commercial oxygen is never free from deleterious products, and should never be inhaled; but this is true, and cannot be too strongly impressed upon the profession. The inhalation of oxygen has been noted by many observers to increase the appetite and materially aid the general nutrition, and by its action upon the pneumogastric and phrenic nerve centers it expands the lungs and reenergizes the diaphragm into vigorous action; and this deepened respiration will sometimes continue for hours after its inhalation. The general glow which follows its use, and the sense of increased vigor which is a sequel to the inhalations, we believe can only be explained as due to an increase in the activity of all nutritive metabolic processes.

Do not make too long administrations of oxygen in neurasthenia, or any chronic disease. Two or three inhalations when the stomach is empty, three times a day—morning, afternoon, and evening—are sufficient in the twenty-four hours. The lungs must first be emptied by strong expiration, then place the tube in the mouth, and while the nostrils are closed draw the oxygen by long and deep inspiration into the lungs; and after retaining the inhalation as long as possible, let it slowly escape from the nose.

There should be an interval of two minutes between the inhalations. Pure oxygen should only be used for local application externally, to stimulate sluggish granulations, etc.

In all forms of disease where there is difficult respiration, and the cyanotic condition, the inhalation of oxygen is the remedy *par excellence*. The cold applications should be made over the spine for half an hour three times a day if the patient does not find them unpleasant, but if so, morning and evening; or even once a day will suffice.

Static electricity may be combined with the use of the ice-bag and oxygen inhalation, if found necessary.

We finish our paper with a reply to the query contained in the title:

Neurasthenia appears to us to be an excessive action in one set of nerve centers, united with an abnormally weak action in the cerebro-spinal or vaso-dilator centers; therefore a mixed condition of neurasthenia and neurosthenia.

*THE COMPARATIVE MERITS OF RESORTS  
IN NEW MEXICO, COLORADO, AND  
ARIZONA.*

By S. E. SOLLY, M.D.

---

We all have heard the saying of Mrs. Malaprop, "Comparisons are odorous;" and I trust I may not be forced to exclaim with Hamlet's uncle, "My offense is rank; it stinks to heaven," but rather may rest with a quiet conscience, having presented you with comparisons redolent of reason, and fragrant with facts.

Of the resorts to be considered, the most northern (Estes Park) is parallel with Philadelphia, while the most southern (El Paso) is on a line with Atlanta, Georgia. El Paso lies in Texas, just beyond the border of New Mexico, but climatically it belongs to New Mexico rather than to Texas, and is therefore so considered in this paper. It is obviously impossible to make mention of all the places in this section of the country which are used as health-resorts. Reference is made only to those which are most characteristic, or to those of which the meteorological data are fullest. In the appended tables I have accorded the substance of all the weather reports obtainable; yet there is much desirable information that at the present time is not forthcoming, and therefore these studies are so far incomplete. The statements made

will be found to be based upon the facts given in the tables and upon the references quoted.

Before proceeding to discuss the differences between these resorts it will, perhaps, be well first to consider in what respects they are similar. Owing to their great distance from the ocean and their relation to the main mountain ranges of the continent, the climate of these States is everywhere extremely dry, with brilliant sunlight and with unusually high solar and relatively; and indeed on the high ground actually, low shade temperatures; the nights are cool and the days warm, quite beyond anything experienced in any other climate at present available for invalids.

The annual means range as follows: Relative humidity from fifty per cent. to forty-two per cent.; absolute humidity between 1.79 grains and 3.25 grains per cubic foot of air; rainfall from seven to sixteen inches; the number of cloudy days from thirty to fifty-seven; and the temperature from 40° at Estes Park to 72° at Yuma. The elevations vary from 7200 feet at Estes Park to 140 feet at Yuma. The latitude extends from 40° to 33°. The annual wind movement ranges from 6663 miles to 3379 miles.

When we come to consider the differences between the climates of these resorts, upon looking at the appended tables it will be noticed that the chief points of distinction are in temperature, wind movement, latitude, and elevation. A comparison between the

temperatures of places of similar elevations shows that latitude does not exert as great an influence as altitude. And in comparing resorts of different elevations it will be seen that altitude is all-important in modifying temperature and, in a less degree, wind-velocity. For these reasons it would appear that the best method of arranging these resorts for purpose of comparison is in the order of their altitude.

As this country lies more or less under the lee of the Rockies it is necessarily dry. In Colorado the bulk of the precipitation occurs in the last two months of the spring and of the summer, while in New Mexico and in Arizona the spring is much drier and the rainfall, which is usually less in amount, occurs both in the winter and in the summer. In all these resorts the autumn weather is about equally dry and bright, and is of a pleasant temperature. In all of them the winter weather is good, being however somewhat more severe as the more northern latitudes are approached. The springs are drier, pleasanter, and less stormy in the southern half of New Mexico and of Arizona than in Colorado and in northern New Mexico.

In Colorado and in northern New Mexico the summer weather in places above 5000 feet is cool and moderately dry, and very pleasant, healthy weather for the visitor and invalid. In southern New Mexico and Arizona, except at elevations of 7000 feet and

more, the excessive dry heat is very trying to all but the robust, as there are only a few invalids whose health is improved by these extreme conditions. A glance at the column showing the night temperatures emphasizes the difficulties to the invalid of the summer climate in the lower and southern resorts of this region. The dust, which is generally abundant and irritating on the lower ground of New Mexico and Arizona at all seasons, is especially so in the summer.

In most of the reports of the health-resorts the character of the soil is not detailed, but inquiry reveals the fact that in many of the resorts, especially on the lower ground of Arizona, the soil is mainly adobe, the towns

being built in the river valleys, so that a great deal of fine alkaline dust arises from the ground in hot, dry weather, while rain or snow will lie upon the surface in cups and hollows for many days longer than it does upon the sandy or gravelly slopes or benches which are generally found situated above the river bottoms; and it is very obvious that the local conditions of these resorts for the most part are very inferior. The majority of the town sites have been chosen for convenience to water rather than for reasons of

\* 1896.

† Total rainfall for Boulder is taken from one year only; September is missing. The wind and humidity of Phoenix is based on one year only.

health, and the difference in the hygiene of a town situated upon a hillside or mesa to one in a river bottom is perfectly astonishing, so that it may be said the environments of many of these resorts are very unworthy of their climates.

What has been said about the town sites is equally true of the accommodations. Most of the towns have not been built for, nor do they cater to, the delicate or fastidious invalid. The lack of interest and amusement or occupation is also a serious drawback in many of these places. And in considering the powerful influence of mind over body, it is most true of the majority of invalids, especially of the consumptive, that

Absence of occupation is not rest,  
And a mind that's empty is a mind distressed.

Before proceeding to give the specific information about the different resorts, it is perhaps well to discuss briefly what is known or believed to be true of the general effects upon health or disease of the chief factors of climate. And as phthisis is the most common and most important of the diseases for the amelioration of which these climates are sought, we shall consider the matter from this point of view. As a broad general statement it may be said that consumption is most prevalent in proportion to the temperature and the humidity of the climate: (1) in damp, cold climates; (2) damp, hot climates; (3) dry, hot climates; and (4) dry, cold climates; while in curative effects it is true in the reverse order. This indicates in a general way that dryness is of benefit, and humidity obnoxious to phthisis, while the relative effects of heat and cold depend upon the degree of dampness. Heat in a damp climate, except when tropical, is less harmful than cold, while heat in a dry climate is less beneficial than cold—that is, always to the vital resistance, and generally to the disease.

"Apparently humidity of the air, apart from other factors, does not in itself produce phthisis. The comparative immunity from consumption among the men of the British navy contrasted with those of the army, and the rarity of the disease in many islands, such as the Faroe, the Shetlands, the Hebrides, and Iceland, show this. The influence of these climates and of sea-voyages on the disease when developed and active has, however, not been shown by the evidence of others nor by my own observation to be advantageous, removals from the sea being generally of most

benefit. Where advantage has been derived from a sea climate it would appear probable that it was owing to the great purity of the air or the elimination of unsanitary conditions and hurtful occupations.

"Dryness of the air, on the contrary, is known to be of positive benefit to the consumptive. The excellent results obtained from desert air (apart from great altitudes, which we shall consider later) are too well known to quote at length.

"In crediting dryness of air *per se* with a beneficial influence upon phthisis, we must not forget that some of the credit, at least, belongs to other necessary accompanying factors of a dry atmosphere, namely, more powerful sunlight and heat, less depressing cloudy weather, cooler nights and shade, and a higher electric tension of the body. What is also of prime importance is the greater opportunity for exercising and resting in the open air, and the free access of fresh air to the house by day and by night while the patient is indoors."\*

*Range of Temperature.*—Hirsch writes that "severe and sudden changes of temperature have no more determining influences *per se* than has the absolute height of the temperature." He shows further, however, that variability, if accompanied by dryness, is usually beneficial; but variability with dampness is positively harmful. These statements are confirmed by the evidence of many other authorities.

*Wind.*—"Consumption is neither more nor less prevalent in a place simply because it is windy, nor are consumptives as a class made better or worse by this element alone. It is beneficial or detrimental according to its temperature and humidity and the patient's condition—that is, according to his need of stimulation or sedation.

"Cold, moist wind sometimes soothes, but more often depresses, the patient, while it aggravates catarrhal affections if they be of a relaxed type.

"Cold, dry wind simply stimulates or else irritates the patient, and hence it improves relaxed catarrhal conditions, but makes those which are inflammatory worse.

"Warm, moist wind lessens irritability, and is either soothing or depressing.

"Warm, dry wind acts as a tonic or increases irritability."†

\* "Handbook of Medical Climatology," by S. E. Solly, M.D.

† *Ibid.*

*Sunlight.* — Sunlight promotes healthy growth, increases the oxidation of tissue, and is a pleasant stimulant to the nervous system. Sun-heat is the best and cheapest of germicides, and is valuable as provocative of open windows and an open-air life. When moderate, it is an agreeable sedative; but when excessive, with dry air, it is very irritating to the nervous system, interferes with the proper action of the liver and kidneys, and prevents the taking of beneficial exercise.

While the dryness of the air makes the sensible temperature lower, yet when the temperature is absolutely high it much increases its irritating and so weakening effects, though at the same time it may be markedly beneficial in drying up ulcerative processes in lung tissues. Excessive heat with dampness is not irritating but far more depressing, and accelerates tuberculous processes.

*Barometric Pressure.* — Hirsch has shown most conclusively that decreased barometric pressure tends to confer more or less immunity from phthisis. The marked decrease which is present in all high climates has been demonstrated by Egger and many other observers to have a remarkable effect upon anemia, by increasing the amount and quality of the red blood-corpuscles and hemoglobin; that these blood changes are brought about, not by the quantities of dryness, sunlight, or other climatic factors in high or other climates, but by the diminished barometric pressure, was proved conclusively by the classic experiment of Regnard, who, at sea-level, kept a rabbit in a bell glass under diminished air-pressure, equivalent to the atmosphere at 6000 feet elevation, for a month. When the rabbit was removed it was found that the same blood changes had taken place as occurred in rabbits transferred from sea-level to a climate at 6000 feet elevation.

The rapid and remarkable improvement in the local and general conditions coincident with these blood changes in consumptives transported from sea-level to high ground of 3000 feet and upwards has been demonstrated by numerous careful observers in Europe and in North and South America. As far as we at present know, the only successful means of combating chronic tuberculosis is by improving the resisting power of the blood; it therefore follows that that climatic factor which most fully and directly brings this result about is the one to be especially regarded in choosing a climate for the cure of consumption. There are, however, other considerations which enter into the question of

the appropriate climate for a given case of consumption: these are mainly the effects upon the heart, nervous system, and the mucous membranes of the respiratory tract; for the climate may be ideal in directly opposing the development of the disease-germs, yet if it mechanically embarrasses the efficient action of the heart or overexcites or depresses the nervous system, or by its stimulation aggravates and increases the irritability of the pneumonic or catarrhal process, or on the other hand by its extreme sedation and therefore depressing effects aggravates them, it may be unsuitable for a given case.

As confirmatory of the general effect of climate in the treatment of tuberculosis as demonstrated by the physiological experiments just spoken of, I refer you to the analysis of some 8000 cases of phthisis treated by climate given in my work upon Climatology. They were all the reports that a careful search through the literature of the subject revealed to me. The number being so large, it may be fair to assume that the law of averages justifies a belief in the general truth of the statistical results attained. The reports are by a number of eminent observers from all parts of the world, and were readily grouped under the following heads: Under the title of home climates are placed those which remained in the same climates in which the disease developed; sea climates (ocean, island, coast—ocean covers only those who took sea-voyages); lowland climates (lowland, sanitariums, desert); highland. The last covers only reports of cases treated in climates above 5000 feet altitude.

The statistics show an almost steady rise in the percentage of improvement from the ocean to the altitudes. The percentage of improvement among those who took sea-voyages was 54 per cent.; in lowland climates, 57 per cent.; in lowland desert climates, 65 per cent.; while in altitudes the improvement runs up to 77 per cent. From this we learn two things: that as a rule the consumptive improves the further he is removed from the sea influence, as shown in the contrast of the percentage of fifty-four and sixty-five; and further, the benefit of altitude over lowlands, even in desert life, is shown by the difference between sixty-five and seventy-seven. Therefore, while the desert air of Arizona will cure more cases of consumption than the sea air of the coast, say of southern California, yet it will not cure as large a proportion as will the mountain air of the highlands.

In deciding what cases are exceptions to these general rules, it will be well roughly to classify cases of phthisis as follows: First, those in whom the tendency to the spread of tuberculosis is the most prominent symptom, which may be called, for convenience, the tuberculous cases. Second, those consumptives in whom there is an especial tendency towards inflammatory processes, and those persons are usually of the erethic temperament; this group may be termed the pneumonic. The third division is those in whom there are catarrhal tendencies of a relaxed or low inflammatory type. Such cases are usually anemic and have phlegmatic temperaments. This group may be termed the catarrhal. It is, of course, understood that all are tuberculous, and most have some tendency towards inflammation or catarrh, or both.

As in the tuberculous cases the important matter is to destroy the germs and remove the anemia, it follows that these cases should be placed on high ground where the air is not only dry and sunny but also cool and stimulating. When the patient is able to exercise, the cooler air, such as found during the winter in most resorts of Colorado, is most desirable, and the cure progresses more certainly and rapidly. The cold acts more beneficially than heat upon the usually depressed nervous system of this class of cases, and also induces greater appetite and increased vitality. When the patients are too feeble to exercise, it is sometimes best to begin their cure in a warmer and lower climate, and later to transfer them to the higher and cooler regions.

With respect to the effect of altitude upon the heart, the tendency in the young towards dilatation from a weak muscle is not a contraindication for the use of a high climate, if the patient is kept extremely quiet for the first few weeks after his arrival. But in persons past middle life, and those in whom the dilatation is accompanied by damaged valves, high climates are dangerous. Valvular disease with good compensation is not necessarily a bar. But time does not permit the discussion of this subject in further detail.

With respect to the effects of altitude and cool air upon nervous irritability, it is necessary to distinguish between the irritability of weakness and the inherent irritability, such as is exhibited in the erethic type. The former are benefited, the latter injured, by altitude and coldness. A desert air benefits,

though in a lesser degree, the first class of cases, and it aggravates the condition of the second class by the excess of heat and dryness. Old age and atheromatous conditions are unsuitable to high and to cold climates.

The extent of lung involved plays an important part in determining the elevation most beneficial to the patient. If marked dyspnea, due to the extent of the lung involvement and not to the anemia or weak cardiac muscle, is present at sea-level, a case with this symptom must be kept on low ground. This particularly applies to obstruction in the left lung.

With respect to the pneumonic cases, the altitude must be moderate, and also the dryness; while in the catarrhal cases the altitude should be a medium one because of the susceptibility to cold-catching from the sudden changes, and also because a greater warmth of air is needed than for the purely tuberculous cases; but dryness is of the first importance.

To turn from this brief consideration of pathological conditions to a short discussion of the different effects of the regions under consideration, it may be said that in the winter climate of such places as Yuma at 140 feet elevation we find the benefits of dryness and heat. At Phoenix (1100 feet) similar conditions prevail, modified as regards local humidity by the irrigation which produces a light morning and evening fog. The heat, however, is not as excessive, and the accommodations and general resources are much better.

At Tucson, 2400 feet up, we still find much of the influence of the desert air with some indications of the benefits derived from elevation. Here the accommodations, while not so good as those at Phoenix, are rapidly improving. El Paso and Las Cruces, 3700 and 3800 feet respectively, are near together and very similar in climate. El Paso is more dusty, and has some of the resources of a city. It is probably more subject to windstorms than Las Cruces, which is better sheltered and cleaner, but less interesting.

Oracle, 4500 feet, forty miles stage-ride from Tucson, is removed from the dust and turmoil of the cities, and is said to be pretty and attractive, with two fair hotels, a pleasant country to ride and drive over, but few interests.

Prescott, 5300 feet, has many points of climate in its favor, but has practically no resources for invalids.

Silver City, 5800 feet, has a remarkably

fine climate, but indifferent accommodations and few interests except mining.

Santa Fé stands at 7000 feet elevation, has a magnificent climate, and is an interesting town with fair accommodations, but unsanitary conditions.

Las Vegas, 6500 feet, has a good winter climate, but the accommodations are inferior.

The Las Vegas Hot Springs, 7000 feet, are in a cañon. There is a fine hotel, which, however, is very seldom open. The place has a good climate, but is monotonous and uninteresting, and the springs are almost negative in their therapeutic qualities.

Cañon City, 5300 feet, is a warm, sheltered, pleasant winter resort. It is a quiet but agreeable little town, and the accommodations are very fair.

Denver, 5300 feet, is colder and more exposed, but probably is somewhat drier and has a better soil than Cañon City. It has the resources and objections necessarily associated with a handsome and progressive city of 150,000 inhabitants.

Colorado Springs, 6000 feet, has about the same winter temperature as Denver, is slightly drier, has less snow, but rather more wind. It was laid out as a health-resort upon a mesa near to, but sufficiently removed from, the shadow of Pike's Peak. It is a handsome residential town without manufactories, and with first-class resources of all kinds, and beautiful suburbs.

Estes Park is a beautiful mountain valley. It is much used by invalids with great benefit during the summer months, and a few have wintered there, finding it at that time monotonous but healthful, and the weather much milder than was to be expected. The accommodations are fair. There are other parks, such as Manitou Park, that are pleasant and healthful for summer residence, similar in climate and in character, but of which no reports are forthcoming. Manitou Park has especially good and attractive accommodations and resources.

In comparing all these resorts, it may be said that Colorado Springs possesses the most stimulating, and Yuma the least stimulating, climate.

The winter and fall climate of all these places is good, and is more bracing the greater the altitude, and the higher the latitude.

The spring weather in New Mexico and in Arizona is, as a rule, much better than that in Colorado.

The summers on the high ground of Colorado are cooler and pleasanter, and they are

as dry as those of like elevations in New Mexico and in Arizona, where the resorts of moderately low elevation are impossible, on account of excessive heat.

There is generally more wind in the more northerly and elevated resorts; the dust, however, is more objectionable in the more southerly and lower resorts, because the soil is usually adobe (clay) and alkaline, and so rises readily in the form of a light irritating powder, while on the high ground the soil is more apt to be gravel or granitic detritus.

---

*THE BENEFICIAL EFFECT OF THE CLIMATE OF SUMMERVILLE, S. C., ON AFFECTIONS OF THE THROAT AND LUNGS.*

---

BY WILLIAM HUTSON PRIOLEAUS, A.M., M.D.,  
Summerville, S. C.

---

To every physician, as the winter season approaches, the question of providing a proper sanitarium for his patients, and one which shall be eminently suitable to their needs, causes much care and anxiety. It is a primary requisite that the climatic conditions of the place resorted to be favorable for the purpose of bringing about the desired results.

Excellence of climate, of course, should be attended by a certain degree of comfort and pleasure, as being conducive to convalescence. Frequently resorts which have obtained a reputation by no means merited are recommended to people as the ideal places where their health may be entirely restored. This is usually the case where companies organized for land improvement have employed all kinds of methods, whether of a questionable nature or not, to exhibit to the world the supposed virtues and advantages of certain places, thereby enabling them (the companies) to secure private gain.

As a practising physician and one naturally interested in promoting and securing the public health, I deem it my bounden duty to set forth as far as lies within my power the unexcelled advantages of climate possessed by Summerville, S. C. I take great pleasure in doing this, cognizant of the fact that as a resort for people in any way troubled with diseases of a pulmonary kind, and also as a place in which to pass the winter months, Summerville to-day stands unsurpassed, though its rivals are numerous. I sincerely trust that this article will meet the hearty approval of many persons interested

in the selection of such a resort and be the means of inducing many to spend the winters in this ideal spot.

In Hare's "System of Practical Therapeutics," vol. iv (just published), page 67, Solly, "On the value of climate in tuberculosis," says: "It is found that, other conditions being equal, consumption is most prevalent in climates in proportion to the temperature and humidity as follows: First come damp cold climates; second, damp hot climates; third, dry hot climates; fourth, dry cold climates; and in promoting recovery from consumption, as a broad statement the reverse order holds good. Thus in a general way it may be said that dampness is harmful to the consumptive, and dryness beneficial."

Again, on page 70, Solly regrets that no results in tuberculosis have been reported from Southern inland places.

It shall be my purpose to give a short account of Summerville, to record so far as I am able the health-giving qualities of its climate, and to mention those classes of cases which derive benefit from spending one or more winters here.

Summerville is situated in the heart of a primeval pine forest, on a sandy ridge, about twenty-two miles from Charleston, S. C. In winter the climate is delightful, the air cool and bracing, and fragrant with the sweet odor of the pine. The town is near enough to the sea coast to cause the atmosphere to lose the aridity of a sandy plain; at the same time sufficiently distant to be free from all dampness. Unlike other places, the local laws prohibit the cutting down and destruction of pine trees. Transgression of any of these laws is always attended with a heavy penalty. The motto of Summerville—"Sacra pinus esto"—is strictly observed by its citizens. Because of this Summerville presents a unique appearance, with its pines growing in the middle of the streets, on the sidewalks, in the gardens, and in fact everywhere,—for where Nature has placed them, there man in his wisdom has allowed them to remain. Here is the long-leaf pine, whose balsamic odor is like life to the poor invalid, and whose tremendous height shields his dwelling-place from the cold wintry blasts. Truly we have an ideal spot for the invalid—pure air, delicious water, sandy soil, and a forest of pines. Hardly ten years ago, at the International Congress of Physicians in Paris, Summerville was spoken of as one of two places for the sufferer from lung troubles to go to. Again, in 1887, Denison in a paper on "The Preferable Climate in

Phthisis," delivered before the Ninth International Medical Congress at Washington, D. C., insisted on "purity, rarefaction, dryness, coolness, with gravelly or porous soil," all of which Summerville possesses to an extraordinary degree.

The average maximum and minimum temperature for sixteen years was respectively 71.6° and 58.9°. Thus, according to Solly and Denison, Summerville with its cool dry climate must be admirably adapted to the needs and requirements of consumptives.

Year by year the number of people who come here is increasing, and the dread of the natives is that too many will discover the health-giving quality of their climate. There is no sanatorium established in the town, but two first-class hotels and many private boarding-houses furnish ample accommodations for visitors.

Summerville's climate cannot bring back the dead to life, neither can it restore to health one in the last stages of consumption; but to sufferers from incipient phthisis, bronchitis, asthma, or the grip, it offers untold advantages. The cool bracing air, filled with ozone and the odors of the pine, acts like magic on mucous membranes and restores them to a normal healthful condition. Summerville is in the center of the "Sunny South," and there are few days when one cannot go into the open air and remain there with benefit to his health. Invalids will find the climate most beneficial from October to May, for during that time there is bright sunny weather and the atmospheric changes are seldom so sudden as to cause any serious anxiety or discomfort.

Besides being a resort for invalids, Summerville's many natural and historic attractions make it a sweet retreat for tourists, and its quietude a healthful resting-place for the nervous and those suffering from insomnia. Many families winter here year after year, for no other reason than to escape the cold of the North and West.

No statistics of cures or beneficial effects to consumptives are available; in my own experience I can recall case after case where patients who have come here either in the first or second stages have improved greatly, but unfortunately I can also mention many sad instances of consumptives beyond human aid being sent here only to be told that they have come too late—and must return at once to their homes.

Man's inhumanity to man  
Makes countless thousands mourn.

This can be applied to physicians who advise patients in the last stages of this dread disease to leave their families and friends to die among strangers. However, I shall not feel that I have written in vain should only one of the many who suffer gain health and happiness from the piny air of Summerville.

*TAKA-DIASTASE AS A NEW DIGESTIVE AGENT.*

BY F. ROBERT BOYD, A.M., M.D., ST. LOUIS, MO.

Chemical manufacturing companies have become so numerous, their literature and samples so plentiful, and their efforts so persistent to foist them upon the medical profession, by the aid of whose influence, in giving them endorsement, they hope to evolve a demand for the same, that the members of the profession have in many instances grown tired, and while they may out of courtesy treat these agents kindly, yet for various reasons they must ignore both their stacks of reprints and their samples. These manufactured products have become so numerous that no physician can afford to give them his time and attention. In every State we find numbers of great manufacturing plants devoted to these various chemical products, each one struggling for the recognition of the medical profession, and to attempt to read all their literature simply means to read nothing else.

We are all creatures of habit, and liable to become more or less extreme in both thought and action, and to pass one means that we pass all; and I think there are few of us who give ourselves up to the candid, thoughtful perusal of any of this literature thrown upon our tables with samples. I think, in fact I know, that the results would in the majority of cases prove fruitless if we did, and thus we excuse ourselves from this task. How much we may lose by not being able or not having time to go over it, and select and appropriate the best of it, we may never know. I am inclined to believe, however, that the really valuable and meritorious of this vast product will in some way command our notice, and under the law of the survival of the fittest sooner or later become recognized.

The idea I am here trying to impress was recently brought to my own mind with such force as to cause me to reflect seriously upon this question, and it has been of such great interest and benefit that I hope I shall be able to secure the attention of other physicians. I believe it is over a year since I

remember seeing the term "Taka-Diastase" for the first time, and since that both samples and reports of cases treated with it have been brought to my attention without my becoming interested in it sufficiently to induce me to prescribe it. I have for the past twelve years been paying special attention to diseases of the stomach and intestines, and have felt that the usually prescribed course for functional difficulties along the digestive tract was about as near perfection as it could be made. The past twenty years has been a history of persistent attempt, with failure, to procure an efficient diastatic ferment. Some of the most eminent chemists of this country and Europe have from time to time set up claims for different inventions, which have not in a single instance proved more valuable than any other pancreatic ferment, and with the exception of a few instances—in malt productions which have manifested a weak diastatic power—all of them have depended upon a pancreatic reaction for their results, and in the hands of the profession they have fallen far short of the claims set up for them, and the hope of both doctor and patient.

I think I am not amiss in stating that the skepticism of the profession in regard to all of the digestive ferments has largely grown out of the fact that neither pepsin nor pancreatin, when introduced into a stomach in which undigested and insoluble starch products have set up an irritation through unnatural fermentation, can render much assistance in giving that stomach or intestine physiological rest. The mistake almost always made is in concluding that the cause of the pain and general disturbance of the function is due to undigested proteids which can be broken up and rendered assimilable by pepsin; but pepsin will do but little if any good. Then the physician, on the theory that either the pepsin is inert, or the presence of fats retards its action, exhibits pancreatin, trypsin, or some other intestinal digestive ferment without proper diastatic power, and again fails; and so his patient goes from one to another, only to meet with disappointment from year to year. I believe that there are many physicians all over this country who have had just such an experience as I here portray, and if I may point out to them a nearer, easier road out of this wilderness than the old beaten path they have been for years pursuing, I shall feel this effort has not been in vain.

My attention was attracted toward Taka-Diastase in a practical way during the last

session of the Missouri State Medical Association, not by any discussion of it by the members of that Association, but by Mr. Takamine himself, who, in the exhibit-room, was conducting a series of experiments with his product, Taka-Diastase, upon thick solutions of boiled starch. I immediately noticed the wonderful facility with which a few drops of the Liquid Taka-Diastase would convert it into a soluble dextrin, only requiring about five minutes to complete the process. The fact that I had on my hands at this time four cases of stomach trouble which were giving me much anxiety made me take a greater interest, I presume, than I otherwise would have done. I had the good fortune to make the acquaintance of this distinguished Japanese chemist, who I soon learned had some valuable knowledge of the function of digestion not made clear in the physiological text-books: for instance, the statement that sixty-five or seventy per cent. of all cases of indigestion are due to undigested starch products, which, escaping solution in the mouth, pass on to the stomach, and not being soluble with the albumens, after a time become local irritants like any other foreign substance.

If this statement be true, it explains why the administration of pepsin and pancreatin so often fails in cases of acute and chronic indigestion. Pepsin under an acid reaction can only attack proteid substances, converting them into peptones, and the pancreatin in an alkaline medium can exert only a very limited influence over starchy substances; hence those starches which escape solution in the ptyalin must remain insoluble, and like other organic substances in the presence of heat and moisture must ferment, bringing on the numerous train of symptoms incident to such action.

Mr. Takamine put into my hands a sufficient quantity of Taka-Diastase to give it a fair trial, and I herewith submit the following report as a result of my experience with it:

CASE I.—Mrs. W., aged thirty-one; married; has five children. She is a delicate woman and has been sick a great deal, and upon becoming pregnant the sixth time called in a midwife, who punctured the membranes. Five days afterward I was called to help her out, and found her nearly exsanguinated, with a small retained placenta (she was perhaps less than three months pregnant). I carefully curetted and douched the womb, expecting her to get along. I was sent for again to relieve the intense burning in the throat and stomach, of which she complained night and

day. She did not rally well, but there were no symptoms of septic poisoning present. I prescribed for her pepsin and willow-charcoal, adding also small doses of powdered nuxvomica, which did little if any good. The result was I was sent for again, and there being no rise of temperature nor any symptoms of septic absorption I gave her a reliable preparation of pancreatin and moved the bowels with Epsom salts. This seemed to afford a measure of relief. Upon the afternoon of the day following, not more than an hour after I had received my sample of Taka-Diastase, I received a telephone message to come to Mrs. W.; she was growing worse every hour. I went expecting new and fearful developments, but found her suffering from the same burning, which she said was simply unendurable. I now took her off every remedy I had before prescribed and began giving her one capsule of three grains of Taka-Diastase every two hours. She had no trouble in twenty minutes after taking the first dose, and has had none since, having made a good recovery.

CASE II.—A married lady, twenty-six years of age. Never pregnant. Came to me for dyspepsia. Said she had been under the care of several other good physicians without relief, until she began to be discouraged. I thought the stomach trouble arose as a reflex from some remote disease, and examined both rectum and uterine organs. I began treating her for chronic cervical endometritis, which for a time promised good results, but was soon followed by the old trouble, seemingly intensified, and do what I would I could get no benefit worth speaking of. Pepsin, pancreatin, charcoal, baptisia, glycogen, peroxide of hydrogen, the mineral acids, and stomach tonics—all proved worthless. Douching the stomach would relieve only while it was being done. The liver refused finally to respond to the more powerful cholagogues, the stools became clay-colored, and I began to fear my patient was beyond help and proposed to her that she go with me to see another physician, which she consented to do. After prescribing Taka-Diastase in Mrs. W.'s case with such good results, I sent the lady word on Friday evening to call upon me, which she did, and I began to give her Liquid Taka-Diastase, which gave her almost immediate relief. She has since that time had the intense gratification of complete relief of all stomach difficulty, and I have proceeded with her treatment successfully.

CASE III.—Mother of the preceding case, who also came to me for stomach trouble. She is sixty years of age, large and robust; has always worked hard, raised a large family, and seen many hardships. She has been sick but very little, but has for two years past suffered much with indigestion. Hemorrhoids have also developed and given her much trouble during the last year. She has gone through the usual experience of resorting to many physicians and remedies without material benefit. Her chief symptoms when she came to me were constipation, excessive dryness, and a feeling of loss of power in the lower bowels, with intense burning pain and bloating, coming on about two hours after eating. I prescribed tablets aloin, belladonna, nux vomica, and cascara sagrada, one at bedtime, and

Liquid Taka-Diastase, 1 fluidounce;  
Essence pepsin, 3 fluidounces.

Mix. Sig.: One dessertspoonful after each meal.

This formula gives the Taka-Diastase time to render soluble all the starches left in the food entering the stomach before the secretion of diluted hydrochloric acid begins, which is about one hour after eating, and by the time the stomach's secretions would destroy the diastase it has accomplished its work and is out of the way. This patient has made a steady gain, which began at once.

The following case is the last, and to me the most interesting, I have had the pleasure of trying this remedy in:

CASE IV.—J. Lathrop Boyd, Esq., my own brother, forty years of age, and prominent in legal circles of the State of Michigan. He has been a sufferer from obstinate stomach trouble since childhood. When a small boy his extreme suffering used to awaken the keenest sympathy and solicitude of the whole family. Everything was done we knew of to relieve him, but with no more than very temporary results. He passed through his boyhood, schooldays, and on up to manhood and professional life with success, but always against the tide. This everlasting pain and burning seemed to hang like an incubus over him. He saw different specialists upon the stomach; none of them could determine anything more than functional difficulty as the cause of his trouble, but nothing they did cured him. Four years ago hemorrhoids developed, for which I operated upon him here in St. Louis, and for a time he seemed better, returning home greatly improved. But the arduous duties of an active law practise soon brought him down again,

and for the last three years he has suffered very much indeed. Some weeks ago he again came under my personal care, at which time he was taking large quantities of soda bicarbonate and common salt in solution, which he stated was the only thing that would relieve the burning. I immediately stopped these, and for the extreme torpor of the bowels from which he had suffered so long I put him on aloin, belladonna, nux vomica, and cascara tablets, one each evening, and powdered Taka-Diastase three grains while eating three times a day, and in two hours after meals ten grains of lactopeptine.

This plan of treatment has seemed to meet the exigencies of his case in a remarkable manner, and he now promises more toward ultimate recovery than ever before.

I think the great good to be derived from Taka-Diastase will suggest itself to any thoughtful physician who has had experience with these intractable cases; its use will surely open up a better knowledge of the function of digestion.

---

#### THE CONSERVATIVE TREATMENT AND THERAPEUTICS OF FALLOPIAN- TUBE DISEASE.\*

---

BY THOMAS MORE MADDEN, M.D., F.R.C.S.E., M.A.O.,  
*Honoris Causa* Royal University; Obstetric Physician and  
Gynecologist Mater Misericordiae Hospital,  
Dublin, etc., etc.

---

In dealing with cases of chronic salpingitis leading to serous or purulent effusions in the Fallopian tubes, the most common origin of which is bacterial invasion, consequent either on gonorrhea or on puerperal sepsis, there can be no special reason for departing from the generally recognized first principles of therapeutics. The primary objects of all treatment, whether surgical or medical, are I presume not merely the removal of actual disease, but also the restoration as far as possible of the structural and functional integrity of the affected parts.

Thus, for example, if the mammary gland were the seat of a purulent collection, or if, as the late Sir Spencer Wells suggested, the case before us was one of hydrocele, would it not be more advisable to open the one or tap the other than to ablate the affected gland in either case? Acting therefore on these principles I have for many years, in the first instance at least, treated by conservative

---

\* Abstract of a paper read before the British Medical Association at Montreal.

measures such as aspiration, together with administration of mercurials and iodide of potassium, a considerable proportion of the cases of pyo- or hydrosalpinx that have come under my observation.

The successful results that may be thus obtained in many, though by no means in all, cases of this kind have been proved in my wards in the Mater Misericordiæ Hospital. Moreover, a preliminary resort to such measures, even if unsuccessful, will not interfere with the results of subsequent salpingo-oophorectomy if that be then necessitated.

The method of aspirating the tubes referred to may be here briefly described. In the first place, to permit the necessary manipulation, the patient should be put under some anesthetic and placed in the ordinary left lateral gynecological position. Then the operator introduces the index and first fingers of his left hand through the sphincter ani upwards and forwards, along the outlines of the posterior uterine wall, the fundus being pressed down by his assistant's hand over the hypogastrium. In this way the tubes and ovaries can be readily palpated, and if there be any inflammation or cystic enlargement of the former, it may be distinctly recognized as a tortuous, elongated, sausage-shaped or rounded fluctuating tumor, extending from the side of the uterus outwards to the broad ligament and backwards into Douglas's fossa. Having thus ascertained the position of the pyo- or hydrosalpinx, the next step is to carefully introduce *per vaginam* on the point of the right index finger a long, fine needle, affixed to the aspirator, up to the roof of the posterior vaginal cul-de-sac. Through this the needle is to be passed into the retrovaginal fossa, and thence guided by the operator's left index from the rectum up to the most prominent presenting part of the tubal swelling, into which it is to be plunged. The tap of the aspirator is then to be turned, so as to give exit to the contents of the dilated tube, the expulsion of which may be assisted by the steady pressure of the assistant's hand from about the hypogastrium down into the pelvic cavity, and continued until the tube is completely evacuated. After this, the cyst cavity should be washed out with an antiseptic, and the vagina should be rendered aseptic by insufflation with iodoform.

Then, no further local treatment beyond hot carbolic irrigation will generally be required, unless the tube should, as sometimes happens, again fill (though probably to a lesser extent), when the same procedure may

be again repeated; until the oviduct has become reduced to its normal size. This procedure should be accompanied with the exhibition of bichloride of mercury in small and long-continued doses, as for example in the following formula:

℞ Hydrargyri bichloride, gr. i;  
Tinct. cinchona comp., ʒ i.

Sig.: Ten drops well diluted after meals.

*Curetting Fundal Orifice of Tubes: Treatment by Electricity.*—The most common immediate cause of cystic accumulations in cases of chronic salpingitis is mechanical obstruction of the uterine orifice of the oviduct, due either to chronic follicular endometritis, flexion, or, in some instances, supra-involution of the uterus. Under such circumstances the tubal obstruction is most likely to be relieved by dilatation, followed by curetting of the diseased proliferating endometrium in the first instance, or by the rectification of the flexion in the second, and by faradization in the last named cases. The faradic current has, moreover, not only in these, but also in other forms of chronic salpingo-oophoritis, been in some instances successfully employed by Dr. Apostoli of Paris, who generally employs in such cases the faradic current of tension applied in moderate doses, and for only a few minutes at a time, for which he claims the most remarkable curative results. Another recent authority on this subject—Dr. Milne Edwards, of Edinburgh—does not believe, however, that the galvanic current is suited to cases where there is definite organic change in the ovaries, but considers that here faradism may possibly be of service.

In those graver, and somewhat more exceptional than is generally supposed, cases in which, from the extent of Fallopian disease, or from the implication in its course of adjoining structures, the urgency of the symptoms attending its progress, or other causes, it becomes impossible to deal satisfactorily or safely with such cases by the methods already referred to, there then only remains for our adoption the complete removal of the uterine appendages. I have elsewhere discussed this operation, of which I have now had sufficient actual experience to enable me to say that unless occasionally imperative and unavoidable it is by no means so universally satisfactory, either as regards the immediate or the remote condition of the patient operated on, as seems to be commonly believed. Without further discussing this topic on the present occasion, however, I shall now

merely add the question of election or necessity I regard as the cardinal point to be decided in considering the expediency of removing the uterine adnexa in the treatment of Fallopian-tube disease. In many instances unquestionably, as I have already said, that course becomes an unavoidable necessity, and is then the obvious duty of the surgeon. But it should not be forgotten, however, that in probably a no less large number of cases tubal disease may also be successfully treated by some of the less heroic but equally effectual remedial and conservative local measures to which I have now referred. These, it may be added, should be accompanied by the internal administration of bichloride of mercury as before mentioned, or by the exhibition of iodide of potash, together with inunctions of oleate of mercury with morphine over the seat of pain.

#### THE TREATMENT OF EPILEPSY.

The *Journal des Praticiens* of April 17, 1897, points out that there are two chief indications in the treatment of this disease: First, the arrest of the paroxysm itself, and second, the determination of the cause and its removal from the patient. In those cases where there is a warning aura which tells the patient of an oncoming attack it is recommended that some means of compression of the part in which the sensation is developed should be resorted to for the purpose of arresting the upward movement of the aura. Sometimes the forced extension or flexion of the arm or leg in which the sensation is developed will abort the attack, and in other cases compression of the carotid artery will have the same effect. It is pointed out that Charcot has counseled the application of ice to the præcordium of patients who have a cardiac aura.

It is of the greatest importance in the treatment of epileptic patients, particularly if they are children, that everything should be done for the maintenance and improvement of their general health and for the training of their mental condition. For this reason close supervision as to their food should be resorted to, and the greatest variety of substantial nourishing articles of diet should be provided. Where the child is rickety the administration of the lactophosphate of lime is often very valuable. Baths and other forms of hydrotherapy are to be recommended for the purpose of improving the tone of the general system. The urinary

secretion and the action of the bowels should be carefully attended to in order that every avenue for the exit of toxins may be kept in active use; particularly is this important in those cases in which there are marked evidences of digestive disturbances with secondary intoxication. In the way of antispasmodics it is thought that camphor, ether, morphine, and belladonna are the remedies which offer us the greatest power for good in the treatment of these diseases, as they are not apt to disorder the digestion, in the opinion of the writer, to the extent that the bromides disorder it. It is also pointed out that Feré claims good results from the nitrate of silver, while Gowers relies largely upon borax and arsenic. It is also claimed that antipyrin not only tends to act as a sedative, but that it modifies the severity of the attack; and sometimes minute doses of picrotoxin are valuable. Notwithstanding all this it remains a fact that bromides are our most important remedies in the treatment of this spasmodic affection. Usually it is best to use small doses of the bromide of potassium, ammonium, and sodium rather than one salt alone. Thus we can prescribe:

℞ Bromide of potassium,  
Bromide of ammonium,  
Bromide of sodium, of each 6 drachms;  
Water, 1 quart.

Order that four to eight teaspoonfuls of this shall be taken each day. Or the following may be given:

℞ Bromide of potassium, 3 ounces;  
Nitrate of pilocarpine, 1½ grains;  
Syrup of bitter orange, 1 pint;  
Water, 1 pint.

A teaspoonful of this may be given four or five times a day.

#### LEAD POISONING WITH DEATH FROM THE USE OF HEBRA'S OINTMENT.

HAHN has recently reported to the Society of Medicine in Prague a curious case in which a child suffering from eczema of the head was treated for a long time with Hebra's ointment. General convulsions ensued, the skin became very pale, the gums presented the characteristic blue line. The patellar reflexes were exaggerated. Finally the child died. The cause of death was confirmed by an examination of the child's body and an analysis of the urine. — *L'Abeille Médicale*, March 27, 1897.

### THE VALUE OF PARACENTESIS PERICARDII.

Progressive physicians are recognizing more and more the fact that effusions into the various serous cavities cannot be satisfactorily removed by the administration of diuretics and purgatives. Even in chronic cases, where there is no necessity for the rapid removal of such effusions, the results rarely justify the exhausting plan of treatment which was so largely resorted to by physicians in the early part of this century. Where the condition of the patient is pressing because of interference with vital functions it is often absolutely necessary for the purpose of saving life to be bold enough to abstract by means of a trocar and cannula, if necessary attached to an aspirating flask, fluid which may be pressing upon the lungs or upon the heart. That paracentesis pericardii is an operation surrounded by far greater difficulties than paracentesis thoracis or paracentesis abdominis is manifest, and those who have had much experience in clinical medicine or in

the performance of this operation have often found it most difficult first to decide positively that the symptoms and physical signs are due to the pericardial effusion and not to dilatation and hypertrophy of the heart. The history of pericarditis, however, the marked increase in the area of cardiac flatness downward to the right and left, the distant and feeble character of the heart sounds, and the evident manifestations of cardiac embarrassment, are at least objective signs which lead the physician to strongly believe that fluid has accumulated in the pericardial sac.

After the difficulties of diagnosis have been put aside the question next arises as to the spot at which paracentesis pericardii is to be performed, and it seems probable that the point of selection is the fifth interspace close to the left border of the sternum, although others have suggested the fourth interspace, and still others that the cannula shall be inserted close to the right border of the sternum in the fifth interspace. The choice of the point for the introduction of the cannula depends very largely, however, upon the physical signs presented by the individual patient, although in the great majority of instances the fifth intercostal space close to the sternum is the area of preference. It having been decided to introduce the cannula in this area, even the most experienced physicians feel timid lest by reason of incorrect diagnosis or other cause they may wound the heart itself; and in some cases they prefer that the patient should die of his disease in the course of a few hours rather than run the chance of saving him on the one hand, or of suddenly ending his life on the other, by puncture of the heart muscle. While there can be no doubt that injuries to the heart muscle are always more or less serious in their possibilities, on the other hand we feel convinced that many physicians have an undue timidity in connection with this possibility. As a matter of fact injuries to the heart muscle itself are not capable of producing any more serious results than puncture or incision of any one of the other muscles in the body, unless the puncture is of such a character as to lacerate or sever a large number of heart fibers or the coronary arteries, thereby interfering with the action of the heart, or unless the puncture tends to strike one of the nervous ganglia in the heart muscle which govern the beating of this viscus. If the latter accident occurs the patient is certain to die, but the probability of this accident taking place must be in the majority of instances decidedly remote. Fur-

ther than this, the insertion of the ordinary trocar and cannula into the pericardium rarely wounds the heart excepting to produce a small punctured wound, which the peculiar crossed arrangement of the muscular fibers in the heart at once closes; and even if the cannula goes so deeply into the heart muscle as to penetrate the cavity of the ventricles and blood is drawn through the cannula, the mesh-like heart fibers immediately close the wound as soon as the cannula is withdrawn. Further than this, unless the cannula is plunged suddenly through the chest-wall and unless the heart is bound down by adhesions to the chest-wall, in the majority of instances the physician will be notified that the tip of his trocar has engaged the heart muscle by the to and fro impulse which is transmitted to the needle of the trocar and cannula by the action of the heart, and the slight withdrawal of the trocar and deflecting it to one side will remove it from the heart muscle and leave its end free in the pericardium, although the heart may still be felt beating against the side of the instrument. Aside from the danger of injuring one of the nervous ganglia of the heart by puncture, the only other danger of wounding the heart muscle lies in the possibility of damaging the wall of the auricle in such a way that free hemorrhage takes place into the pericardium, the patient dying not so much from loss of blood as from distention of the pericardium and consequent pressure upon the heart muscle; for the auricular wall not being so well provided with thick muscular fibers is more easily penetrated, and wounds are by no means so easily closed. That our position in regard to the danger of wounds of the heart muscle is correct is proved by the gradually increasing array of reports in current medical literature concerning cases of stab-wound or other wounds of the heart in which patients permanently recovered or lived for many hours or days after the injury, dying from some secondary affection. One of the most recent of these cases is that which is reported by Williams in the *New York Medical Record* of March 27, in which a man received a stab-wound three-fourths of an inch to the left of the sternum, which penetrated the chest and produced a small punctured wound of the heart about half an inch to the right of the right coronary artery and between two of its lateral branches. In this case, however, there was no hemorrhage from the heart or pericardium, but profuse hemorrhage from the internal mammary vessels. The hemorrhage from these vessels was controlled by

operative procedures and the patient recovered, notwithstanding a sharp attack of pericarditis and pleurisy.

Again, the writer of this editorial has seen paracentesis pericardii attempted in a case in which there was great dilatation of the heart with pericardial adhesions, and it was found that there was no pericardial effusion. The trocar and cannula, however, passed into one of the cardiac cavities and one or two ounces of blood was aspirated into the bottle before the injury to the heart was recognized. On the next day, the symptoms of pericardial effusion being considered still more marked, it was decided to perform the operation a second time, and once again one of the cardiac cavities was tapped and pure blood was withdrawn. In each instance the withdrawal of the blood seemed to relieve the distention and congestion of the heart, and was followed for a number of hours by marked relief to the patient.

#### THE DANGER OF CHLORATE OF POTASSIUM.

---

For many years the medical profession, with but little knowledge of the pathological conditions connected with diphtheritic infection, and with still less information in regard to the influence of chlorate of potassium upon the human body, were in the habit of employing this drug in large quantities in the treatment of diphtheria, some using it because it was supposed to exercise a favorable influence upon the local diphtheritic process, both when it was swallowed and when it was eliminated by means of the salivary glands; others, still more ignorant of its influences, employed it with the ridiculous idea that it was capable of yielding oxygen to the body and so supporting the system; while still others believed that the additional oxygen which it gave forth actually aided in the elimination of the effete products of the disease and thereby enabled the patient to resist its ravages. With our increased knowledge concerning the bacillus of diphtheria and the pathological changes which its toxins produce in the body, this method of treatment became less and less popular, and finally, when the profession grasped the idea that chlorate of potassium was not the innocent drug that it was thought to be, its use in diphtheria became still more limited. We have reason to believe, however, that there are still quite a number of physicians who continue to employ it either as a matter of routine practise or because they

are unaware of its deleterious influences. The literature of medicine will be found to contain as each year goes by more and more cases in which the abuse of this remedy produces poisonous influences in the body, which are recognized to-day, although put down to other causes years ago. The object of this note is to insist upon the fact that the chlorate of potassium is, next to the cyanide of potassium, the most poisonous of the potassium salts. As an instance of this we may quote a case which recently occurred in Vienna, in which a boy of sixteen who was suffering from sore throat was given a gargle consisting entirely of chlorate of potassium. Either because of misunderstanding of the orders or through inadvertence the patient swallowed a considerable amount of the drug and death speedily resulted, the inquest revealing all of the usual signs of death from this substance.

---

#### THE PROPER CARDIAC STIMULANTS IN THE PRESENCE OF PERICARDIAL EFFUSION.

---

We have often pointed out in the columns of the THERAPEUTIC GAZETTE that the physician must be careful in the administration of remedies to see to it that no pathological condition exists in the body which renders the action of a given medicament useless or even harmful. Our attention has been called to the matter of the administration of cardiac stimulants in the presence of pericardial disease by an able paper which was recently read before the Association of American Physicians during the Congress in Washington in May, 1897, by Dr. Frederick C. Shattuck of Boston. In the course of this paper and its discussion the point was made that digitalis could be given with advantage to patients suffering with pericardial effusion with consequent cardiac failure, but from this view the writer of this editorial distinctly disagreed. Aside from the changes which may take place in the myocardium and in the visceral layer of the pericardium in the course of the various infectious processes which usually produce a pericarditis, certain physical conditions arise which are largely responsible for the very evident cardiac difficulties from which patients often suffer. The chief of these physical causes for impaired heart action in a certain proportion of cases is undoubtedly the large quantity of fluid which has been poured out into the pericardial sac, and which so presses upon the heart

and distends the pericardial sac that the function of the cardiac muscle is only carried out with great difficulty. That the presence of the effusion is the chief factor in the production of faulty heart action under these circumstances is not only proved by ordinary processes of reasoning, but is confirmed by the fact that in those cases in which successful paracentesis of the pericardium has been performed the heart has been very much relieved, for a short time at least, or until the effusion has formed again, and has performed its function with an approach to that found in health.

There is no doubt that cardiac stimulants are of value under these circumstances. The question simply arises as to which one to employ, and of all those in which we have confidence it seems to us that the least favorable is digitalis, simply because the physiological action of this drug is to greatly increase the diastole of the heart, enlarging its cavities, and making it fill the pericardial sac much more completely than it frequently does under normal circumstances. In other words, digitalis, by increasing the dimensions of the heart during diastole, really adds to the difficulties of this viscus, which is already pressed upon by the effusion which is in the pericardial sac. Certainly it seems much more rational to employ in such cases not digitalis but some remedy like strychnine or strophanthus, alcohol or ammonium, which will support the heart, increase the activity of the circulation, and yet not materially alter the space which is required within the pericardial sac for normal cardiac activity.

---

#### THE SURGICAL TREATMENT OF CHRONIC GASTRIC ULCER.

---

A most valuable paper on this subject is contributed by Mikulicz to the *Berliner Klinische Wochenschrift*, No. 23 to 25, 1897, suggested apparently by von Leube's exhaustive thesis upon the limitations and results of the medicinal treatment of comparatively recent, non-complicated ulcers of the stomach.

Even in these cases operative intervention has been suggested by both physicians and surgeons. In a case of Leucke's the operation was undertaken for the relief of intolerable gastralgia and exhausting dyspepsia. By means of a gastro-enterostomy this patient was cured.

Hitherto, cases which have come to the surgeon have been in such a depressed con-

dition from starvation and bleeding that active intervention of any kind was extremely dangerous. None the less the results have been surprisingly good. They would doubtless be much better were operation undertaken at an earlier period.

In considering the advisability of operation for non-complicated ulceration of the stomach the surgeon should give due weight to the danger of operation and should be assured that by the use of the knife the patient can be decidedly benefited. Unfortunately, statistics do not enable us to judge accurately as to the mortality of gastric ulcer not subject to operation. The mortality figures vary from five to thirty per cent. It is fair to conclude from the result of autopsies that three-fourths of all gastric ulcers heal spontaneously. Many of these cases, however, ultimately die because of stenosis from cicatricial contraction, or from phthisis greatly aggravated by the ulcer, or from malignant disease.

Gerhard states that in from three to five per cent. of cases death occurs from hemorrhage; in thirteen per cent. from perforation; in ten per cent. from stenosis of the pylorus.

Debove and Raymond give a mortality of fifty per cent. In 100 cases they find that death occurred from tuberculosis in twenty, from peritonitis in thirteen, bleeding in five, inanition in five, and other complications in seven.

Mikulicz holds that when all complications are considered the mortality will range between twenty-five and thirty per cent. He believes that surgical intervention is always indicated when internal treatment proves unavailing.

As to the mortality of operation: Of 238 cases of pyloric stenosis and gastric ulcer without serious complication operated on in the clinics of Billroth, Czerny, and Mikulicz, there was a mortality of 21.8 per cent. The operations performed were resections of the stomach, gastro-enterostomy, and pyloroplasty. The mortality of the resection cases was greater than that of those subjected to gastro-enterostomy and pyloroplasty. It is worthy of note that defects in technique are rarely the cause of death, but rather this is attributable to the extremely reduced condition of patients.

It may be said as a result of this statistical study that the danger to which a patient with an open uncomplicated ulcer of the stomach is exposed is decidedly greater than the danger which he would run if subject to a well-directed operation.

When medicinal treatment has failed opera-

tion is imperatively demanded. Surgeons heretofore operated mainly for the relief of the pyloric stenosis, whether this was due to a cicatrix of an old ulcer or was associated with an open sore. It is proved beyond controversy that relief of the stenosis is followed by healing of the ulcer, the stomach completely recovering its motor and secretory functions in a few months at most. These patients gain rapidly in weight and strength and become completely able-bodied. A similar success attends the operations on ulcers not complicated by stenosis. Küster's two cases in which intervention was required because of bleeding recovered very promptly, as did two patients operated on by Mikulicz.

Gastro-enterostomy is credited with having healed a number of discharging gastric ulcers, but to this operation Mikulicz greatly prefers pyloroplasty. He found in a number of cases the pylorus greatly narrowed, not from cicatricial contraction, but from tetanic spasm of the muscular fibers. In two cases the ulcer was first excised and the fresh surface covered by mucous membrane, which was sutured over it, after which pyloroplasty was performed. In the four cases operated on the quantity of hydrochloric acid markedly diminished. Before operation it was double the normal, but rapidly lessened; in two cases it was normal within five months.

It is evident, then, that gastric ulcer can be cured by surgical intervention without attacking the lesion directly, but by making the rapid and complete emptying of the stomach into the duodenum possible; whether the narrowing be due to scar tissue or to muscular contraction, pyloroplasty is equally indicated. As to the choice of operation, resection of the pylorus and a portion of the stomach is by all odds the most dangerous and least authorized method of radical cure. Circular resection should be abandoned in cases of ulcer, unless there is a suspicion of carcinoma. The author has observed five such suspicious cases, in which he performed the operation.

As to the choice between gastro-enterostomy and pyloroplasty in the treatment of open gastric ulcer, since both accomplish rapid and complete emptying of the stomach-contents into the bowel, the preference should be given to that which is easier and least dangerous. Hence pyloroplasty is distinctly to be preferred. It is not indicated in all cases, however. Thus, if the pylorus is fixed or if its walls are densely infiltrated the operation will be extremely difficult.

As to the technique of the operation, the anterior wall of the stomach and duodenum should be incised to the length of two to two and a half inches. The suture of this wound at right angles to its length makes a wide communication and one which facilitates the physiological evacuation of the gastric contents.

This cannot be said of gastro-enterostomy, following which there may be only established a vicious circle, the stomach-contents passing into the bowel and thence toward the pyloric valve rather than away from it, and returning to the stomach. That this has actually occurred is shown by autopsy, a spur-formation preventing the ingested matter from passing into the ileum. There is no certain way of preventing this spur. This vicious circle Mikulicz attributes to muscular spasm rather than to spur-formation. In one case reported by the author in which this spur-formation was attended by intractable vomiting, a second abdominal section was performed and entero-anastomosis was established in a distended loop of bowel between the seat of gastro-enterostomy and the pylorus and a loop of gut below this point. This method of procedure is the only certain one by which the vicious circle may be prevented. When at the time of operation the stomach is found markedly atonic, gastro-enterotomy should, as a rule, be supplemented by this second operation.

The surgical complication of gastric ulcer which has been most frequently subject to operation is pyloric stenosis. The indications for operation and the technique are well known. Another complication requiring operation is adhesion of the base of the ulcer with the parietes or surrounding organs. Loose adhesions usually cause a chronic mild perigastritis—sometimes violent gastralgia.

The diagnosis between simple gastralgia and gastric ulcer is extremely difficult. Operation and freeing of adhesions cause in these cases complete relief of pain.

Cases in which after adhesions to the parietes the ulcer gradually penetrates are readily recognized. A hard tumor is formed which can be readily mistaken for carcinoma. It is usually associated with symptoms of ulcer, and the pain is extremely violent and is greatly increased by palpation of the swelling. Operation is absolutely indicated in these cases. The ulcer, together with the infiltrated portion of the belly-wall, should be resected and the resulting wounds closed

by suture. Usually the stomach can be dropped back into the abdominal cavity. Of the eight cases collected by the author all were successful.

The most serious complication of gastric ulcer is perforation. From 1885 to 1894 thirty-five cases were operated on, with thirty-four deaths, a mortality of over ninety-seven per cent. From 1894 to 1896 sixty-eight cases were operated on, with thirty-six deaths, a mortality of about fifty-three per cent.

The prognosis in these cases depends upon whether the stomach was full or empty. Hence it follows that when perforation is feared nothing should be given by the mouth. Statistics show that cases of cure are four times as numerous when operation is performed in the first twelve hours as when it is postponed. The wisdom of the policy of waiting until the first shock has passed by before resorting to operative intervention is open to grave doubt. This shock is extremely likely to run on to fatal collapse. About eighty per cent. of perforating ulcers are placed in the anterior belly-wall, hence are accessible. Some are so placed that they cannot be reached, at times cannot even be found. None the less, cure has resulted from peritoneal tampon drainage.

As to treatment, excision is not necessary unless the ulcer is so placed that the procedure is extremely easy. The rent should be closed by suture. Often even this is not possible, either from location of the ulcer or because of the brittleness of the tissues due to inflammatory infiltration. In the latter case a portion of the omentum may be set over the rupture, or this can be closed by a sack of iodoform gauze.

In addition to the acute peritonitis set up by sudden perforation, there is a chronic peritonitis beginning as perigastritis, due probably to a very small opening closed by adhesions with neighboring parts. These adhesions gradually yield and a fibrino-purulent progressive peritonitis develops, at first confined to the region of the stomach, finally spreading through the entire subphrenic portion of the peritoneum. The diagnosis of this condition is difficult. The slighter cases heal spontaneously. The operation is likely to be extremely difficult.

Probably the most frequent complication of gastric ulcer is bleeding. When a large arterial branch is eroded a search should be made for it. In but two cases this search has been successful; one of these was treated by

the author. In three other cases operation was performed for the relief of bleeding. Because of inflammatory infiltration, checking of bleeding by ligation was impossible, hence the thermo-cautery was used. In case of hemorrhage the ulcer is usually placed in positions unfavorable for intervention. Only a very large vessel is liable to lead to life-threatening bleeding, and this is generally a vessel in the substance of the pancreas. A number of cases are recorded in which it was found impossible to find the seat of the ulcer. While the advisability of operation may be fairly questioned in case of sudden violent bleeding because of difficulty in diagnosis and difficulty in finding and securing the vessel when the ulcer bleeds repeatedly for a few weeks and months, there can be no question as to the desirability of operating.

---

## Reports on Therapeutic Progress

---

### *THE TREATMENT OF INGROWING AND INGROWN TOE-NAILS.*

In the *New York Medical Journal* of March 20, 1897, J. L. ANDREWS contributes an article on this practical subject. He first gives a definition of what we mean by an ingrowing toe-nail, and says it is a condition in which one or both sides of the great toe-nail seem to grow downward and press into the soft parts to an extent sufficient to cause pain on pressure, and more or less discomfort while walking. This condition is considered by some to be always due to a rolling upwards of the soft parts over the side of the nail, rather than an actual deformity of the latter.

As a matter of fact we see both conditions, and it is important to distinguish between them before giving a prognosis or selecting a line of treatment.

Where the soft parts are primarily at fault we may promise our patient a permanent cure, without operation, if our directions are carefully followed. Sometimes it will be only necessary to order a proper shoe. This shoe should have a low, broad heel, to prevent a wedging forward of the foot while walking. The inner side should be straight, to prevent pressure on the corresponding side of the nail. The toe should be sufficiently broad and extend far enough beyond the end of the foot to prevent pressure on the outer side from above and in front. If this is not sufficient, pack a small amount of cotton under the edge of the nail to protect the soft parts, and apply a strip of rubber adhesive

plaster diagonally around the toe, in such a manner that the soft parts shall be drawn away from the nail without direct pressure over the latter. For this purpose a semi-lunar-shaped piece of plaster is often better than a straight strip. It should be applied with the convexity forward, one horn beginning just behind the nail on the affected side. This will allow the belly to catch the offending soft parts, while the rest of the piece is carried around the plantar surface of the toe and over the dorsum, crossing the first end. This dressing should be changed every three or four days.

In the first class, where the nail is really deformed, this plan is of very much less value. But many cases will be held in abeyance if we attend to the shoe, apply a cotton protection under the edge of the nail, encourage it to grow out beyond the soft parts, and keep them clean. However, this will sometimes fail, and the nail will become really ingrown. Neglected cases of both varieties almost invariably reach this stage, and this explains why, in dispensary practise, we nearly always see the latter variety.

Here there is always more or less hyperplasia of the soft parts, which are rolled up over the side of the nail in amount usually proportionate to the length of time the trouble has existed, and the amount of irritation present. Next to the nail there is a mass of granulation, discharging more or less pus. In nearly all these cases our treatment must be operative if we effect a cure, and in all of them it will be found the most humane procedure.

A modification of the method devised by Anger seems to fulfil the indications more perfectly than any other. He removes a wedge-shaped piece, including the offending side of the nail, all of the granulation tissue, and more or less of the hyperplastic soft parts. This leaves a flap with which to cover the raw surface. Anger secured the flap with adhesive plaster, put the patients to bed for a week, and did not let them walk for ten or twelve days. By the method about to be described the patients walk immediately, do not go to bed, and are generally discharged cured in from ten to fourteen days.

The success and comfort of the operation depend almost entirely upon little points of technique, and the writer gives them in detail:

The toes and foot are first scrubbed with soap and water, followed by a solution of bi-chloride of mercury (1:1000). For anesthetic

sia, ten to fifteen minims of a two-per-cent. solution of cocaine hydrochlorate is sufficient if distributed in the following manner: Introduce the hypodermic needle from before backward, just under the part of the nail to be removed; as soon as the skin is pierced inject a drop or two, and wait a moment before pushing it further; repeat the process until the root of the nail is reached. Withdraw the needle now, and, beginning near the primary puncture, distribute a few drops in the skin and soft parts along the outer side of the nail, nearly as far backward as the first joint. In this way the only pain felt is while the primary puncture is being made, and even that may be done away with by spraying with ethyl chloride or ether.

Next wind a small rubber tube around the base of the toe, to prevent blood from interfering with our work. Before making an incision swab the whole granular area thoroughly with pure carbolic acid, working it well down under the edge of the nail. Failure to do this will often cause infection and delayed union.

The first incision begins anteriorly somewhat beyond the edge of the nail, and is carried directly backward (separating a sufficient amount of the side of the latter) to a point a fourth of an inch behind the true matrix. This is deepened through the underlying soft parts, well down by the side of the phalanx.

The second incision begins anteriorly at the same point as the first, and curves outward and backward to join the posterior end of the primary incision. This is deepened through the soft parts around the outside of the nail until we reach the lowest part of the first incision.

Remove the wedge thus set free and search the posterior part of the wound carefully, so that no part of the corner of the nail or matrix shall be left. If we leave a piece of nail, immediate trouble will ensue; if only the matrix is left, another ingrowing nail will make its appearance in a few weeks.

If properly fashioned, the flap which we have will fit the opposite raw surface perfectly, and should be secured by one or two catgut sutures in front of the nail and the same number behind. Before removing the rubber band apply a moderately thick pad of gauze over the flap and bind it tightly to the toe with a few turns of gauze bandage. Now remove the rubber tube and complete the dressing.

The patients walk home, and although

there is often some pain the first night it does not last longer, and they keep about with little discomfort. The dressing should not be changed in less than a week, unless there is some indication, and at the end of ten days or two weeks the cure will usually be complete.

The "Cotting" operation has, perhaps, been more frequently used in this class of cases than any other, and it has two strong points: it is very easy to do, and the ultimate results are nearly always good. In point of time it suffers in comparison, as the healing process requires from three to ten weeks. Another objection to it is the often painful process of changing the dressings every two or three days.

The second class of ingrown toe-nails, fortunately rare, will take but little of our time. Here the suppurative process has existed for a long time, and we have on either side and in front extensive hyperplasia, sometimes enough to almost bury the nail from sight. The nail is also lifted more or less from its bed, sometimes nearly as far back as the true matrix. The suffering is exquisite, and it is often impossible to wear any kind of a shoe.

A flap operation is here out of the question; the proximity of a suppurating surface which we must leave will defeat almost any attempt at primary union that we may make. Instead, we should pare off the hypertrophied parts on either side as in the "Cotting" operation. In front the part should also be trimmed down to the level of the bed of the nail.

In dealing with the nail itself we should be guided by the conditions present. If it is loosened nearly to the matrix, it would be better to pull it out and pack the socket with gauze; if the latter precaution is not taken the new nail will find contracted quarters when it comes out. Where the anterior and lateral parts of the nail are separated for only a moderate distance, the free part should be trimmed off to prevent the collection of pus. In these cases the healing process usually requires from four to twelve weeks.

#### A RESEARCH UPON ANESTHESIA.

In the *Journal of Experimental Medicine* for March, 1897, WOOD and CARTER publish the results of a research and conclude:

1. Lowered arterial pressure has a comparatively feeble effect upon the respiration, but when the pressure falls sufficiently, respiratory depression does occur.

2. Even excessive lowering of blood-pressure primarily stimulates the vaso-motor center, the sensibility of the center being evidently necessary to the automatic regulation of the circulation.

3. The circulation recovers itself more slowly after profound etherization than after a like chloroform narcosis.

4. It is possible for ether as well as chloroform to produce death some hours after the cessation of its administration, at a time when the cerebrum has long freed itself from distinct evidences of the narcotic, so that consciousness and intellectual action have been restored.

In applying these conclusions to the subject of practical anesthesia it is evident that the depression of the circulation produced by chloroform has effect upon the respiratory centers only when the pressure has fallen very low; and whilst it may be a factor in the production of respiratory failure during chloroformization, the failure must be chiefly due to the direct influence exercised by the drug upon the respiratory centers.

Clinical experience shows that nausea and general depression are more pronounced after the use of ether than after the use of chloroform, a difference which is strongly insisted upon by the advocates of chloroform as an important agent in favor of that anesthetic. Our research confirms clinical observation, and experimentally shows that the depression of the circulation produced by ether is more permanent than that caused by chloroform, the reason probably being the large amount of ether which is necessary to produce profound narcosis, with lowering of the arterial pressure,—an amount so large that it can neither be burned up in the system nor yet eliminated in the time which would be necessary for the much smaller amount of chloroform to be gotten rid of after chloroformization.

#### *DANGERS OF ANTIPYRIN IN ERYSIPELAS.*

In *L'Abeille Médicale* of March 27, 1897, it is pointed out by SPANOUDIS of Port Said that persons suffering from erysipelas seem to be peculiarly susceptible to antipyrin. It usually causes anuria and a profound fall of temperature, which have needed the administration subcutaneously of caffeine, and hot applications. As this has happened more than once to Spanoudis he believes that erysipelas is one of the infectious diseases in which antipyrin is contraindicated.

#### *INTERSTITIAL INJECTIONS OF METHYLENE BLUE IN EPITHELIOMA OF THE FACE.*

In the *Normandie Médicale* of April 1 M. DUBARRY relates the following case: The patient, a woman fifty-seven years old, stated that eighteen years before she had noticed a pimple of about the size of a pin's head on the right side of the chin. For ten years it had remained in about the same condition. She had never been alarmed until one day when, on scratching the spot, which had itched for some time, she provoked a hemorrhage that lasted for four hours. She then consulted her physician, who advised a little operation, but the idea of an operation frightened her, and she allowed seven years to pass before again consulting a physician. During the last two years of this period the disease had greatly increased, and the pimple had attained the size of a fifty-centime piece; the itching also had become more frequent and persistent, and the spot often bled, especially when the patient removed the scabs which covered it. An operation was again advised, but as there was no suffering the patient would not submit to surgical intervention. A year later the tumor had spread so rapidly that she decided to seek the advice of another physician, who, in view of the extent of the disease, strongly urged upon her the necessity of an operation; but she resolved not to have it done. Two years more passed, during which time the disease had progressed so rapidly that she became alarmed, and again sought the advice of a fourth physician.

At this time the scabby surface of the epithelioma occupied the entire right side of the chin from the hollow as far as the middle of the horizontal ramus of the maxilla; vertically, it extended beyond the fold of the lower lip, and beyond the body of the maxilla. The surrounding tissue was red, hard, and edematous, and the lip was much thicker on the diseased side. The tumor was divided into four lobes, each one of which was covered with bloody scabs. When the author tried to separate them a rather large quantity of bloody pus was discharged; he found also that the tumor was adherent to the periosteum of the maxilla.

An operation was urgent, but owing to the cowardice of the patient and the great loss of skin which would have resulted, and which would have been difficult to replace, the author resolved to try interstitial injections of methylene blue, although without any hope

of success. He used a ten-per-cent. solution in distilled water, and during the first applications he injected as much as thirty grains. Each time he saturated the entire diseased surface, pushing the needle as deep as possible until it touched the periosteum, and throwing the liquid in all directions. This was repeated as often as necessary. The tumor and all the red tissue surrounding it became of a bluish color. Several times hemorrhages were provoked, but they were not alarming or of long duration, and a slight compression rapidly arrested them.

After the first application the intense itching completely disappeared. During the first three months the author practised an injection regularly every two days, the average quantity of liquid injected being fifteen grains. After a month of this treatment the tumor noticeably diminished in size. After the third month it had diminished one-half; cicatrization occurred from the periphery toward the center. As recovery approached a more considerable resistance was felt; the tissues became more compact and denser. During the fourth and fifth months of the treatment only one or two injections a week were practised; the quantity of liquid used was also diminished in proportion as recovery advanced, and during this stage not more than two or three divisions of a Pravaz syringe were filled for the injection.

In the beginning of this treatment, when the quantity of liquid injected was very large, the urine became of a decided blue color, which disappeared gradually, and it was sometimes twenty-four hours after the injection was practised before the urine regained its normal appearance. At no time did the patient feel pain in the kidneys or experience trouble on micturition. In June, 1896, the treatment was stopped, five months after the first injections. In February, 1897, there was a firm cicatrix on the spot where the epithelioma had been, which was crossed in all directions by fibrous bands which were very resistant to the finger and adhered to the maxilla. The cicatrix was scarcely larger than a two-franc piece.

With regard to a complete recovery, the author states that up to the present time all the indications lead him to think that recovery will be permanent. Even if a relapse should occur, the same treatment may be resorted to again.

Methylene blue, says the author, seems to possess peculiar properties which are capable of making a profound change in the diseased

cell or in the microbe which produces this affection. He is convinced that this mode of treatment will render great service not only in superficial cancrs, but in the deep cancerous affections, notably of the face; provided, however, the diseased spot can be put in contact with the medicament. Each diseased element should be saturated with this therapeutic agent until the noxious principle is profoundly charged with it.—*New York Medical Journal*, May 1, 1897.

#### THE THERAPEUTICS OF METHYLENE BLUE.

The *Medical Record* in its issue of April 24, 1897, speaks editorially upon this subject, and points out that until comparatively recent times blue pyoktanin was known as a local and general remedy in the treatment of inoperable malignant growths. Our readers are familiar with the varying success in carcinoma and sarcoma which has followed the use of this remedy as well as methyl violet in the hands of different observers since Mosetig in 1890 first advocated its employment.

Among the many diseases in which pure methylene blue has been more or less largely employed as an internal remedy may be mentioned acute and chronic Bright's disease, gastric hyperacidity, malaria, headache, diphtheria, cystitis, and gonorrhea. In the first Netchaieff, among others, has reported favorable results, even to the disappearance of albumen and hyaline casts from the urine, along with general improvement in various directions. Berthier has stated that it may be given with advantage in indigestion attended with pain, vomiting, and hyperacidity; the dose recommended is from one to three grains daily for several days, followed by a few days of rest, when it is to be resumed. Conflicting reports have been made upon the value of the drug in malarial affections by Guttman, Ehrlich, Muehl, Lava, Mya, and others. In many instances it has seemed to act very beneficially, while in others it has failed. Lewy recently claimed in the *Berliner Klinische Wochenschrift* that marked relief follows its administration in various forms of headache, especially angiospastic migraine, nervous cephalalgias, and especially the head pains of neurasthenia. The relief is not alone temporary, but in many instances lasting. Ten doses of one and one-half grains each usually sufficed for a cure.

In diphtheria the use of the remedy either

as a local application or internally has seemed to be overshadowed by antitoxin and other methods of treatment. Recently several observers have advocated the remedy in acute gonorrhea, and Moore (*British Medical Journal*, January 16) has seen it cut short the acute stage and decrease the suffering. Allen has reported great improvement in some instances of chronic cystitis, and this in spite of the fact that several observers have noted strangury when the drug has been pushed; and Mya as well as Lewy advise powdered nutmeg to be given at the same time to prevent bladder irritation. The usual dose is one decigramme or one and one-half grains in capsule once, twice, or thrice daily. The urine becomes blue or greenish within five hours of the initial dose, and remains so for several days after the last dose has been given. It must be remembered that toxic symptoms may be produced, and in all instances it is well to give it in tentative dose until the patient's susceptibilities are tried. Methyl violet and impure pyoktanin are most apt to cause vomiting or other disagreeable symptoms.

---

*ZITTMANN'S TREATMENT BY HOT AIR  
AND DECOCTIONS IN SYPHILIS.*

In *Treatment* of April 8, 1897, COOPER contributes an article on this topic. He states that he has met at various times in his practise a certain number of cases of tertiary syphilitic ulceration which ran a very rapid course, the destruction of tissue being produced by phagedenic inflammation. This phagedenic inflammation cannot in the writer's opinion be deemed as solely due to the syphilitic poison, and it is very probable that other factors contribute to its production. Thus, given an individual who has contracted syphilis, and whose general health is destroyed by alcoholism, by tuberculosis, by malaria, or by any other cause, these are the cases in which we may expect tertiary ulceration to supervene, and in which this ulceration is more likely to take on phagedenic action.

After a large experience in this class of cases the author has come to the conclusion that the syphilitic element, although producing the primary ulcerative process, is not a very strong factor in the phagedena, for if this were so we ought to expect the administration of mercury or the iodides *secundum artem* to produce a rapid amelioration of the symptoms. But this is not so; on the contrary it will generally be found that the exhibition of these drugs, either singly or in

combination, has not only no effect in staying the ravages of the process, but will greatly increase the destruction of tissue. Nay, the author goes further than this, and states that even after the phagedenic ulceration is stayed and healing has taken place, the administration of antisyphilitic remedies may reproduce the symptoms. He has seen this occur over and over again, and particularly wishes to emphasize this point.

The phagedenic process may occur at any part which is the seat of tertiary ulceration, the destruction of tissue taking place very rapidly, a few days frequently sufficing for the total destruction of the nose or the penis, should either of these parts happen to be the seat of the disease. It behooves us therefore to be very prompt with our treatment, in order that this deplorable condition of affairs may not result.

The nose is a very favorite organ to be attacked, and this may be partly due to a deficient circulation in that organ when exposed to cold.

Where the phagedena attacks the penis, the body, or the limbs, and the face remains free, one of the best modes of treatment consists in the continual warm-bath treatment; but where the nose is affected this method is obviously inapplicable. When this organ is attacked it is most necessary to have at our hands a method of treatment which will rapidly cut short the process, as if it progresses the results from an artistic point of view only are most deplorable, for unless the condition is recognized early, and efficiently treated, total destruction of the soft and bony parts of the nose will very rapidly ensue, and there can be no more disgusting sight than a noseless man, unless indeed it be a noseless woman, for even the most successful plastic operation can never gloss over the defect.

The writer has for some years been in the habit of prescribing in these cases a course of Zittmann's treatment, and in his opinion it is the very best remedy we have at our command for arresting the rapid destructive process of syphilitic phagedena. Under this course the destruction of tissue is rapidly stayed, the wound becomes healthy, and cicatrization of it promptly follows. As the writer has now seen and treated by this method a very large number of cases, he is desirous of placing the results of his experience upon record, hoping they may be of some benefit and service to those who may happen to have cases of a like nature.

The Zittmann treatment consists in keeping the patient in a room at 80° F. and administering certain decoctions according to a prescribed rule. For the reason that he finds a large number of practitioners have difficulty in discovering the really correct method of using this remedy—for this means of treatment is unfortunately generally ignored in surgical text-books, as well as in monographs dealing with syphilis—he appends the details as described in his work on Syphilis.

The course of treatment extends to a fortnight, during which time the patient is put upon a strict diet and regimen. The decoctions and pills are made from the following formula:

#### ZITTMANN'S DECOCTION NO. 1.

℞ Rad. sarsæ. cont., 3 iv;  
Sem. anisi,  
Sem. Fœniculi, 22 3 j, 9 j;  
Fol. senna, 3 j;  
Rad. glycyrrh. contus., 3 iv.

And in a linen bag:

Sacchar. alb.,  
Alum. sulph., 22 3 j;  
Hydrarg. subchlor., 3 j, 9 j;  
Hydrarg. bisulph. rub., 9 j;  
Aque Cong., O vj.

Boil gently down to one gallon, strain, and put into four forty-ounce bottles. Label "The Strong Decoction."

#### ZITTMANN'S DECOCTION NO. 2.

To the dregs from No. 1 decoction add:

Rad. sarsæ. cont., 3 ij;  
Cort. lemon.,  
Sem. cardam.,  
Rad. glycyrrh., 22 3 j;  
Aque Cong., O vj.

Boil gently down to one gallon, strain, and put into four forty-ounce bottles. Label "The Weak Decoction."

℞ Hydrarg. subchlor., gr. ij;  
Ext. coloc. co., gr. v;  
Ext. hyoscyami, gr. ij.

Ft. pil. ij. Label "The Pills."

The patient is kept in a room at 80° F. The diet consists of: Breakfast—Boiled egg or bacon, tea; no sugar or spices. Lunch—Butcher's meat, vegetables; no fruit. Dinner—Soup, fish, poultry.

The evening before beginning the treatment the two pills are taken, and the next four days, at 9 A.M., 10 A.M., 11 A.M., and 12 M., half a pint of the strong decoction drunk very hot. At 3 P.M., 4 P.M., 5 P.M., and 6 P.M., half a pint of the weak decoction cold.

The patient is kept in bed, except for one hour every evening. On the fifth day he is allowed to get up; he may have a hot bath, and dress, and is allowed, if he asks for it, a little brandy or whiskey and soda.

In the evening two pills are administered, the patient starting the decoctions the next day as before. So the treatment goes on until the fifteenth day, when it is discontinued.

The following case illustrates the points which Cooper desires to insist upon, viz., that antisypilitic remedies do more harm than good; that when healing has taken place their administration may cause a relapse; and lastly, that in Zittmann's course of treatment we have a very efficient method of staying the phagedena.

Mr. C., aged thirty-one, was under the care of Mr. Huxley for extensive tertiary ulceration. The ulcers were scattered over the body, scalp, limbs, and penis. The penis became the seat of phagedena, and Mr. Butlin was called in. Later on the writer was asked to see the patient with Mr. Huxley. The patient first noticed ulcerations on April 3, 1894, and he consulted Mr. Huxley April 10. Patient went into a nursing home, but in spite of treatment the ulcerations showed no signs of healing, but gradually grew worse. He was treated with tonics and one grain of mercury with chalk three times a day.

The phagedena rapidly spread and destroyed the body of penis. On May 19, 1894, he was first seen by Cooper, and continuous warm-bath treatment commenced. When out of the bath tartrate of iron lotion was applied to the phagedena sores. Cod-liver oil was given internally. All mercury and iodides were stopped. Under this treatment the patient grew gradually better, and the sores healed, so that on July 6 he was able to go to Margate under the care of Mr. Treves. About the middle of July patient was given a mixture containing iron and perchloride of mercury.

Very soon after this the nose broke down, and by the middle of August all the other sores had broken down. The mercury was discontinued, and Fowler's solution substituted. The nose healed up by September 29, but broke down on October 6. Perchloride of mercury was again prescribed, which was taken until November 20, when patient left Margate and came back to Mr. Huxley, who asked the writer to see him; the latter found the whole of the soft parts of the nose and the cartilages of the alæ were destroyed. All the other sores had broken down, and the ulceration was rapidly spreading. He ordered him to go immediately into a Home, and have a course of Zitt-

mann. Accordingly on November 22 the Zittmann treatment was commenced. The wounds gradually took on healthy action, and by the end of the fifteen days' course were well on the road to healing.

On December 13 the ulceration of nose was looking healthy. Skin-grafting was performed.

January 2, 1895, patient left for his home; all places quite healed.

The author saw patient in February, 1895. All wounds still healed; so he suggested a plastic operation for the nose, which was done by Mr. Bloxam, and proved very successful. At the present time (March, 1897) the patient is perfectly well, and has no sign of any return of his trouble.

#### PARALYSIS AFTER CHLOROFORM.

TASSE has recorded two cases personally observed by him, in which paralysis followed chloroform narcosis. He believes that such paralysis arises from several causes: First, from the position in which the patient is lying, whereby pressure is exercised upon a supplying nerve, or as a result of tractions on the arm or leg of a violent nature. Second, the employment of impure chloroform, which seems capable of poisoning the nervous system and producing such paralysis, at the same time developing transient or permanent albuminuria. He also believes that in some rare instances the chloroform renders the patient susceptible to microbic intoxication, with secondary paralysis from this cause.

#### SOMATOSE IN THE TREATMENT OF PERSISTENT VOMITING OF PREGNANCY OR AFTER ANESTHESIA.

In the *Journal de Médecine de Paris* of April 18, 1897, LUTAUD records his experience with somatose in the treatment of these conditions, first calling to mind the fact that somatose is not a medicament but is intended for nutritive purposes. Thus in one case a woman at the fourth month of pregnancy vomited with such persistence that grave emaciation and exhaustion came on, and it was thought that it would be necessary to bring on labor. Nothing remained on the stomach, and finally nutritive and rectal injections were resorted to and artificial serum was also given. At this time the idea occurred to the writer to use somatose. At first a small teaspoonful diluted with a small quantity of water was well borne,

and gradually the quantity was augmented until after a week four teaspoonfuls of somatose could be taken. Vomiting stopped, the stomach began to be able to retain various liquids, and finally it was possible to administer milk, cocoa, and various soups which had been fortified by the addition of somatose. He then details four other cases of a somewhat similar character, concluding with one in which there was grave anemia following loss of blood due to metrorrhagia and traumatic hemorrhage. Lutaud believes that this form of nutrition is valuable in many of these cases.

#### THE VALUE OF DOVER'S POWDER.

In the *Journal des Praticiens* for April, 1897, is an article by LIEGOIS upon Dover's powder. He first points out that this substance will very frequently relieve the pains, and cure, at least for a considerable period of time, muscular rheumatism; the doses varying from five to ten grains for this purpose. Many years ago French physicians were in the habit of administering from one to two grains of this powder to children of four to six years who were suffering from subacute articular rheumatism. He also believes that it is a remedy capable of doing very great good in measles and scarlet fever, since by the perspiration which it induces it aids in the development of the rash, and quiets the fever and nervous agitation. In certain cases it is well to administer it with sulphur. Thus a prescription may be written containing Dover's powder and washed sulphur, of each two or three grains. This will tend to move the bowels and will also exercise a favorable influence upon any catarrhal process which may be present in the body. In cases of influenza Liegois believes that Dover's powder is exceedingly useful in relieving the pain and inflammation of larynx and bronchi, the pain in the limbs, and many of the other characteristic concomitant symptoms. As a rule it is sufficient to administer two to three grains of the Dover's powder three times a day. Sometimes the following prescription is advisable:

℞ Dover's powder,  
Sulphate of quinine, of each 2 to 4 grains;  
Powdered hyoscyamus leaves,  $\frac{1}{4}$  grain.

Make into a pill or cachet and administer one or two each day.

In case of pulmonary congestion complicating the eruptive fevers the internal administration of small doses of Dover's powder is very beneficial. Again, in certain

cases of diarrhea in adults or children, particularly if they have been exposed to heat, the combination of Dover's powder and mercury with chalk is useful. Thus we may prescribe Dover's powder one grain, mercury with chalk one grain, and extract of rhubarb one or two grains. A pill containing these quantities of these ingredients may be given three or four or more times a day. In diarrhea dependent upon tubercular enteritis cachets containing the following prescription may be used:

- ℞ Dover's powder,  $2\frac{1}{2}$  drachms;  
Compound chalk powder,  
Calumba powder, of each 5 drachms.

To be made into 60 cachets, and two or three are to be taken each day.

#### FORMALDEHYDE SOLUTION IN THE TREATMENT OF DISEASES OF THE NOSE, EAR, AND LARYNX.

An abstract in the *Revue de Thérapeutique* of April 15, 1897, of an article published in a Russian journal by YATCOUTA describes the results which he has obtained in the treatment of these affections by the use of formaldehyde gas solutions. In the treatment of laryngitis and chronic nasal affections he places a five-per-cent. solution of formalin in a glass carafe and instructs the patient to inhale the vapor which arises therefrom on shaking the vessel. This treatment is carried out two or three times a day and lasts from five to ten minutes. He asserts that in the treatment of acute laryngitis the results are most favorable, a complete cure being arrived at in from seven to twenty-four hours in the sixteen cases in which he tried it. In three cases of acute coryza the condition disappeared in twenty-four hours after the use of three or four douches of a weak formaldehyde solution. He also believes that in catarrh of the Eustachian tube the use by means of a Eustachian catheter of formaldehyde solution is of value. The employment of this treatment produces a sensation of burning and tingling in the nose or in the throat, and sometimes cough. There is also apt to be some irritation of the conjunctiva, with coryza.

#### A PRESCRIPTION FOR ASTHMA.

The *Journal de Médecine de Paris* of April 14, 1897, gives the following prescription:

- ℞ Tincture of opium, 1 drachm;  
Sulphuric ether, 2 drachms.

Fifty drops every half hour until the patient is relieved.

#### THE ANTIGALACTAGOGUE INFLUENCE OF CAMPHOR.

At a recent meeting of the Society of Medicine of Nancy HERRGOTT read a paper upon this topic and remarked that Ténissien found that antipyrin possessed antigalactagogue influence as long ago as 1890. The method which Herrgott employs is to diminish the quantity of the patient's drink, to administer purgatives, and to place over the breast which is to be treated an ointment or liniment of camphor. When antipyrin is used for this purpose ten- to fifteen-grain doses twice or three times a day are needed, but Herrgott asserts that this use of antipyrin has never given him favorable results, although he admits that the danger is not as great as one would suppose. The camphor may also be given internally in the dose of one or two grains once, twice, or thrice a day, and it is asserted if the external and internal treatment are both resorted to the decrease in the secretion is quite remarkable.

#### TREATMENT OF SEXUAL ATONY IN THE FEMALE.

The *Journal de Médecine de Paris* gives the following prescription:

- ℞ Extract of cannabis indica,  
Extract of nux vomica, of each 30 grains;  
Aqueous extract of aloes, 7 grains;  
Make into one hundred pills and take three a day.

#### INFANTILE ECLAMPSIA OF GASTRO-INTESTINAL ORIGIN CURED BY HYPODERMOCLYSIS.

In *La Presse Médicale Belge* of April 25, 1897, NAUWELAERS reported a case of this character, his attention having been called to an earlier communication of Solé in which was recorded the treatment of a case of puerperal eclampsia by this means.

On the 27th of December he was called to see a child aged seven weeks, who was being nourished by means of sterilized milk. The patient had been suffering from obstinate constipation, although it had gained considerably upon this diet. The abdomen was tense and painful and there were evidences of great nervous irritability, so that the child seemed to be on the border of a convulsion. On the next day the child had vomiting and green diarrhea, suffered greatly from colic, and was evidently in continual pain. On the 29th it was no better, and received some calomel. On the 30th the calomel produced vomiting, and the next day the child refused

to nurse and seemed quite ill. Three days later, at three o'clock in the afternoon, the child was taken with violent convulsions, and passed into a condition of profound collapse. Before the physician's arrival a hot bath had been given without very material modification of the patient's condition, and one week after it was first taken ill it was seized with a series of convulsions of considerable severity. The vomiting became frequent, there was somnolence interrupted by sharp cries of pain, the fontanelles were depressed, and the pulsations were very feeble. The child received some albumen water and later some bicarbonate of sodium, benzo-naphthol, and salicylate of bismuth; frictions were applied to the abdomen by means of chamomile oil. After three injections the bowels were moved. The next day the convulsions had disappeared, but later on returned. The patient afterward became desperately ill and passed into a state of collapse. Under these circumstances it was decided to inject normal salt solution into the subcutaneous tissues. This was done, with extraordinarily good results. The convulsions ceased, the general condition of the child improved, and ultimate recovery took place. The injections amounted to as much as two-thirds of a pint in eight hours. Altogether a considerable number of these injections were found necessary before they could be stopped.

---

**THE TREATMENT OF FETID BRONCHITIS AND PULMONARY GANGRENE  
BY HYPOSULPHITE OF SODA.**

The *Revue de Thérapeutique* of March 15, 1897, records the fact that DUMAS has employed this treatment in a large number of cases of bronchiectasis and in tuberculosis with cavities for the purpose of combating the fetid character of the expectoration and modifying the septic condition of the bronchial tube. He has employed creosote, guaiacol, myrtol, menthol, and a large number of other substances, such as eucalyptus and turpentine, but has obtained the greatest advantage from the use of the hyposulphite of sodium. He claims that this substance may be taken each day in the dose of from two to three drachms without difficulty; that it is eliminated partly by the urine and partly by the lungs. He has found that as much as half an ounce acts as a laxative and half as much more as a purge. Its action is not immediate. He considers that the hyposulphite of sodium is contraindicated where there is a

tendency to hemoptysis, and for this reason it has to be used with some caution in pthysical patients with cavities. It does the most good in modifying the character of the expectoration in gangrene of the lung, being particularly useful in those cases which arise from traumatism, from the inhalation of irritant or toxic materials, or from gangrene of the lung complicating other diseases.

---

**THE USE OF ICHTHYOL IN SMALLPOX.**

*La Médecine Moderne* of April 21, 1897, tells us that KOLBASSENKO has highly recommended dressings containing ichthyol in the treatment of smallpox. It is employed in the following manner: As soon as the papules appear the skin is anointed with the following prescription:

℞ Ichthyol, 3 drachms;  
Oil of sweet almonds, 2½ ounces;  
Lanolin, 5 drachms.

Or,

℞ Ichthyol, 1 drachm;  
Vaselin, 1 ounce.

This allays the itching and the pain, and modifies the degree of suppuration, and seems also to decrease the pitting.

---

**A SKIN ERUPTION DUE TO ANTIPYRIN.**

*L'Abeille Médicale* of March 27, 1897, tells us that LYON has reported to the Society of Therapeutists in Paris the case of a woman of thirty-three years, who several hours after the ingestion of antipyrin developed a general pemphigus-like eruption upon the skin and also upon the buccal mucous membrane. This condition lasted for ten days. There was also a scanty urine, but no albuminuria.

Blondel reported a case in which the eruption was accompanied by a stomatitis; and Goldschmidt of Strasburg is recorded as having seen edema of the lower extremities and the vulva, with blebs forming under the skin, as a result of full doses of antipyrin. All these symptoms ceased when the drug was stopped. In the discussion which followed the report of these cases Lyon expressed the opinion that they were only apt to occur in those persons with renal lesions.

---

**DROPS FOR ATONIC DYSPEPSIA.**

℞ Tincture of nux vomica, 2½ drachms;  
Resorcin, 7 grains.

Mix and take five to ten drops three times a day.

## HYPNOTICS FOR CHILDREN.

In *La Tribune Médicale* of April 21, 1897, COMBY is reported as considering this question in a clinical lecture. After pointing out the necessity of proper hygienic surroundings and feeding in the treatment of restlessness and sleeplessness in children, he proceeds to a consideration of the drugs which may be employed, such as orange flowers, chamomile, and similar gastric stimulants and nerve sedatives. He also calls attention to the fact that in certain cases codeine may be administered in syrup, and that even morphine and laudanum may be required. As a rule, however, the ordinary sedatives are much better than these pain relievers. The disadvantage of employing the bromides is that they stupefy the patient; very often tincture of musk ten to twenty drops, asa-fetida, valerian, Hoffman's anodyne, or a few drops of cherry-laurel water, will be sufficient to produce sleep. If chloral is employed it may be given in the dose of one grain for each year of the child. Or chloralamide may be used in the following prescription:

- ℞ Chloralamide, 10 grains;  
Syrup of orange flowers, 1 ounce;  
Water, 2 ounces.

Two teaspoonfuls an hour apart before going to bed.

In other cases a prescription composed as follows may be used:

- ℞ Bromide of potassium,  
Chloral, of each 30 grains;  
Fluid extract of hyoscyamus, 30 minims;  
Fluid extract of belladonna,  
Fluid extract of cannabis indica, of each 1 drachm;  
Syrup of orange flowers, 1 ounce;  
Elixir aromatic, 1 ounce.

A small teaspoonful for two doses before going to bed.

Comby thinks sulphonal should be administered in the dose of three or four grains to a child of three or four years. Trional seems to act equally well. Thus he cites a case of a boy two and a half years old who was attacked with scarlet fever and suffered from marked nervous excitement and insomnia, in whom five grains of trional produced a peaceful and quiet sleep during the entire night.

In another case, a girl of three years, convalescing from scarlet fever and suffering from insomnia, received the same dose of trional repeated for three days, with the result that useful sleep was produced. He then cites other cases in which it was equally useful.

[After reading this article we would like to call attention to the fact that very rarely is it

necessary or advisable to administer such powerful hypnotics to children, unless it be in the course of some one of the acute infectious diseases when the nervous symptoms are most manifest. In our experience proper regulation of the diet and avoidance of excitement prior to bedtime produce all the results that can be desired.—ED.]

THE SUBCUTANEOUS INJECTION OF  
GUAIACOL CHLOROFORM.

*La Médecine Moderne* of March 10, 1897, states that COLLEVILLE has employed hypodermically a solution of guaiacol and chloroform in the proportion of six parts to ten. This is to be injected directly into a painful point in the dose of from fifteen to thirty drops, and has proved itself peculiarly useful in the treatment of nerve pains such as sciatica. If as much as fifty minims are given the injections are sometimes followed by induration, which, however, gradually disappears.

These injections are preferable to the morphine injections, and are to be preferred to rubbings and frictions.

PRESCRIPTIONS FOR CREOSOTE AND  
NAPHTHOL.

MAXIMOWITCH in the *Deutsche Archiv für Klinische Medizin* records his use for five years of these substances in the following prescriptions. As Alpha-naphthol is very strong he usually uses Beta-naphthol. But, on the other hand, he sometimes gives Alpha-naphthol as an intestinal antiseptic, with castor oil, as follows:

- ℞ Alpha-naphthol, 45 grains;  
Chloroform, 5 minims;  
Oil of peppermint, 2 minims;  
Castor oil, 3 drachms.

The dose of this for a child of from three to ten years is one to three teaspoonfuls. He finds it useful in dysenteric diarrhea and choleraic discharges.

Tablets are prepared as follows:

- ℞ Alpha-naphthol, 5 grains;  
Powdered rhubarb, 1 grain;  
Extract of belladonna,  $\frac{1}{4}$  grain.

One or two of these tablets are taken at a dose several times a day. In cases in which there are arthritic tendencies or oxaluria, or the uric acid diathesis, he is apt to combine with this tablet small doses of aloes or podophyllin, and in typhoid fever the dose of naphthol is increased from twenty to sixty

grains a day. He also believes that it is useful in the local treatment of erysipelas in the proportion of one per cent., and in laryngitis or tubercular laryngitis a spray may be used in the strength of ten per cent. The following prescription may be employed when it is advisable to use creosote:

- ℞ Creosote, 3 drachms;  
Alpha-naphthol, 45 to 60 grains;  
Powdered iodine, 3 grains;  
Cod-liver oil, a sufficient quantity to make 6 ounces.

Half a teaspoonful of this may be given each day to a child of ten years. Or the following pills may be given:

- ℞ Creosote or guaiacol, 3 drachms;  
Iodoform, 15 grains;  
Eucalyptol, 1 drachm;  
Arsenous acid, 1 grain;  
Strychnine, 1 grain;  
Sulphate of atropine,  $\frac{1}{4}$  grain;  
Extract of gentian, and  
Gum arabic, a sufficient quantity to make up 100 pills.

Three or four of these pills may be taken each day.

#### THE TREATMENT OF DIABETIC COMA.

In *La Semaine Médicale* LEPINE, of Lyons, reports still another case of diabetic coma treated with success by two drachms of chloride of sodium and two and a half drachms of bicarbonate of sodium in one quart of sterilized water.

#### A POWDER FOR CORYZA.

- ℞ Subnitrate of bismuth, 1 drachm;  
Powdered camphor, 10 grains;  
Powdered boric acid, 30 grains;  
Hydrochlorate of morphine, 1 grain;  
Hydrochlorate of cocaine, 1 grain;  
Powdered benzoin, 15 grains.

A pinch of this is to be snuffed up the nostrils.

#### THE TREATMENT OF CARDIAC ARRHYTHMIA.

In *La Médecine Moderne* of March 17, 1897, HUCHARD contributes an interesting article upon this subject. He first considers those cases of cardiac arrhythmia which are not to be treated by digitalis or by cardio-vascular tonics. Most of these cases arise from the excessive use of coffee or tobacco or alcohol, and can be cured by regulation of the diet or drink, the disturbance being either due to the direct effect on the nervous mechanism of the heart or to the irritation of the gastro-intestinal tract. In cases of tobacco heart

there are very frequently evidences of pseudo-angina pectoris. In other cases, too, the condition of arrhythmia is to be removed by removal of reflex irritation such as diseases of the gastro intestinal, uterine, or hepatic systems. In those cases in which there is organic disease of the heart, on the other hand, it will often be found that the gastric disorder is due to an imperfect circulation. Nevertheless, in these cases marked benefit may be obtained by improving the condition of the stomach by the administration of alkalies or hydrochloric acid, according to whether there is too great acidity or lack of acidity in the gastric juice. In nearly all these cases, unless there be marked feebleness of the heart, digitalis is contraindicated, and this drug by irritating the stomach may actually make the condition worse.

Many cases are more benefited by the administration of bromide of potassium and atropine than by the administration of digitalis. Finally, in ordinary intermittence of the cardiac action digitalis, as a rule, will be found absolutely useless.

The second class are those in which digitalis and cardiac tonics are advisable. These are the cases in which the symptoms are continually present and in which there is an insufficiency of the mitral valves and an arterial change. If, however, there be much myocardial change digitalis does little good, and in its stead strophanthus is to be employed. In the arrhythmia which is sometimes seen in the aged, digitalis must be employed with caution, because of atheromatous changes in the blood-vessels; and where it is not considered wise to employ it, it may be necessary to give other cardiac tonics, such as sparteine, in the dose of one-half to one grain several times a day, at the same time reducing blood-pressure by the use of a milk diet and nitroglycerin. If, as already pointed out, there is marked myocardial degeneration associated with the arrhythmia, digitalis does little good. Many of these cases are much benefited by an absolutely rigid milk diet. The last set of cases are those in which there is an excessive arterial tension. This usually occurs in persons with atheromatous changes, and because of these changes and the high tension digitalis rarely does them good, at least until sufficient doses of nitroglycerin have been used to render the arterial tension approximately normal. In all these cases, however, the regulation of diet and the maintenance of a normal gastric action is absolutely essential.

*THE USE OF HYPODERMOCLYSIS IN THE  
TREATMENT OF CHOLERA INFANTUM  
AND THE HEMORRHAGE OF THE  
MENOPAUSE.*

In the *Journal de Médecine de Bordeaux* for April, 1897, DUKODIE considers the value of artificial serum injections in these conditions. He first cites some of the original literature in regard to their employment, particularly concerning the strength of the solutions that should be employed. In pressing cases intravenous injections are to be resorted to. As a rule one and a half quarts is quite a sufficient quantity either for hypodermoclysis or intravenous injections, whether the condition be one of hemorrhage or one of shock or toxemia.

[This quantity has usually been found quite sufficient in our experience.—ED.]

*THE TREATMENT OF TYPHOID FEVER  
BY GUAIACOL.*

In the *Journal de Médecine de Bordeaux* KETCHER records brilliant results which he claims to have obtained in twenty-nine cases of typhoid fever by the use of guaiacol. In all these instances he believes that the course of the disease was considerably modified by its employment, either when used internally or externally.

*HYDRASTIS CANADENSIS IN THE TREAT-  
MENT OF BRONCHIAL CATARRH.*

In the *Centralblatt für Innere Medizin* of May 1 Dr. M. SAENGER, of Magdeburg, gives his impressions of hydrastis as a remedy for bronchial catarrh. It seems that some six years ago he prescribed it for a patient whom he was treating for a tuberculous affection of the larynx and apex catarrh, the immediate occasion of its employment being a trifling hemoptysis caused by the patient's lifting a heavy weight. Four days later Dr. Saenger saw the patient again, and learned from him that for three days there had been no blood in the expectoration, and furthermore, that a tormenting cough with which he had suffered had completely disappeared, the expectoration had become decidedly less, and the character of the sputa had changed in that they were far less frequently greenish and tenacious than before. The patient, a man of intelligence, imputed all his improvement to the use of the medicine that had been ordered for him.

Although Dr. Saenger himself was properly skeptical as to this point, he tried hydrastis

on another phthisical patient, not for the purpose of checking hemoptysis, but to mitigate a troublesome cough with great difficulty of expectoration. In this case, too, there was great improvement. For the most part the sputa lost their purulent admixture and became thinner. The patient declared that the medicine had given him more relief than he had obtained from the morphine, codeine, Dover's powder, apomorphine, and other like drugs that had previously been ordered for his cough. His night's rest was no longer disturbed by coughing, he could breathe easier and deeper, he felt stronger, and he was better able to attend to his business. As in the first case mentioned, physical examination of the thorax showed a notable diminution of the bronchial catarrh.

Subsequently Dr. Saenger used hydrastis in a great number of cases of bronchitis, including those not dependent on the tuberculous trouble. He found that in the initial stage of acute bronchial catarrh it was quite ineffectual, but that in the subsequent course of the disease it was beneficial, especially if the course was protracted and the sputa had lost their purely mucous character and assumed a muco-purulent aspect. He found the remedy particularly efficacious in chronic bronchitis, for it mitigated the cough strikingly, facilitated expectoration, changed the muco-purulent character of the sputa to a more mucous one, and decidedly diminished the physical signs.

As compared with opium and its derivatives, says Dr. Saenger, if hydrastis is not quite so prompt in its action in checking the cough, it is more enduring and its final effect is greater, for it acts upon the cause of the cough, producing a more or less complete disappearance of the catarrh. As an expectorant, it is at least equal to the other expectorants and solvents that are in use. So far as can be judged from physical exploration of the chest and from examination of the sputa, it far excels the other antibronchial drugs in use. He states that he could not do without hydrastis now in the treatment of bronchial catarrh, acute as well as chronic, for it enables him to dispense with the use of opium and its derivatives almost entirely in the treatment of tuberculous subjects.

He has employed it in the form of the fluid extract almost exclusively. To adults he gives twenty, twenty-five, or thirty drops four times a day, in a little sweetened water. In case it does not produce the expected effects, larger doses may be used. He has

not found hydrastinine so trustworthy as the fluid extract. He has never observed dangerous or unpleasant effects from the doses of the fluid extract mentioned, but he remarks that very large doses may give rise to angina pectoris in the subjects of heart disease and in very debilitated persons.—*New York Medical Journal*, May 15, 1897.

#### INJECTIONS OF IODOFORM INTO AND AROUND TUBERCULAR JOINTS.

GILBERT BARLING writes to the new journal *Treatment* about this therapeutic method, and says that the positive demonstration that many of the so-called strumous lesions coming under the care of the surgeon are really tubercular seems for a time to have upset the minds of some surgeons. They preached a crusade of extremely active treatment of many of these lesions, and especially of tubercular joints; indeed, they wrote and spoke as though tubercular joints were little more amenable to measures, other than operative, than malignant disease itself. Now that the new name for the old disease has become more familiar, we are able once again to recognize that tubercular joint disease is as a rule very amenable to treatment, and that the great principles of rest and immobilization, thoroughly carried out, bring patients through their troubles safely—often with practically healed joints. Whilst this is generally so, it happens in a certain number of cases, either from want of rest or from feeble tissue resistance in the patient, that the disease is progressive, and some supplementary treatment is needed to hinder its progress and to obviate the necessity of future excision or amputation. It is impossible here to discuss the many remedies which have been advocated. The writer proposes to deal with one only, of which he has now had several years' experience without any drawback, and from which in some cases he has seen very great advantage.

The remedy of which he writes is iodoform, injected into or around the affected joint. He has now discarded ether and olive oil as the vehicle for solution or suspension, and always uses glycerin, with a little water added if it is very thick. Suspended in the fluid is ten per cent. of iodoform, practically none of which is actually in solution. To the fact that the iodoform is not really dissolved, as it is in ether, is due no doubt the immunity from iodoform poisoning, from which none of the author's cases have suffered.

As to the method of injection and the preparation of the emulsion: The writer has often injected the fluid without sterilizing it, but as an extra precaution latterly he has had it heated for half an hour in a water-bath. The iodoform lying at the bottom of the fluid is not lost by volatilization. The emulsion is best freshly prepared. The syringe should be one capable of holding not less than six drachms, of being taken entirely to pieces, and it should be supplied with coarse needles as the emulsion is rather thick; all parts should be boiled just before use. The amount to be injected varies from one to five or six drachms, according to the age of the patient and the joint involved. For instance, into the knee-joint of a child of five or six years two or three drachms may be introduced; into the corresponding joint of an adult, twice that amount. It is not always necessary to inject into the joint cavity; greater advantage is often obtained by injecting into the thickenings of the tendon sheaths around, as in the wrist-joint, or into the pulpy thickenings produced by the tubercular infiltration penetrating the joint capsule, such as occurs in the front of and behind the great trochanter in the hip-joint. In these cases smaller quantity of the emulsion is used.

The immediate effect of the injection into a joint cavity is to set up a good deal of effusion, the swelling increasing for about twenty-four hours. This may cause a considerable amount of pain, and the temperature rises from two to four degrees, but by the fourth day it generally becomes normal, the pain disappears, and the swelling also in about ten days. If the injection is only into the tissues around the joint the local and general disturbances are much less marked. The injection may be repeated, either exactly into the same part or more often at one adjacent; but he has been in the habit of allowing at least a fortnight to intervene before repeating the attack.

It goes without saying that this is no remedy for tubercular lesions in the bones, such as are inaccessible to the emulsion; when, however, we have superficial caries of the ends, secondary to destruction of cartilage from synovial invasion, he believes the effect is valuable. It is, however, in the granulation thickenings, with caseation of the synovial membranes, tendon sheaths, and other soft structures around the joints, that the best effects are seen. The diminution of swelling, and the loss of the elastic semi-fluctuating feel that these tubercular forma-

tions produce, and eventually their disappearance, are the indications of the value of the remedy. How the effect is produced, whether by a specific action of the iodoform on the tubercle bacilli, or merely by the fibrosis produced by the irritation of the emulsion, he has no room to discuss; but his results with iodoform injections are very much better than those he has obtained with zinc chloride—so much so that he has discarded the latter. Every one is of course familiar with the difficulty in arriving at the correct conclusion as to the value of drugs in the treatment of disease. The statistical method has so many weak points that it is of no value here; the judgment of the individual surgeon must be taken for what it is worth, and he has no hesitation in saying that many of his cases have derived great benefit from injections of iodoform emulsion in tubercular joint disease. Rest and fixation are carried out by the writer thoroughly. If the cases are not doing well he resorts to the injections, still keeping the part at rest. If improvement now takes place instead of progress of the disease—a change he frequently sees—surely there is every justification for speaking well of the use of iodoform, seeing that the only altered condition is the injection of the emulsion. All cases do not benefit, and he is not able to distinguish positively what are the conditions under which the emulsion will do good.

If evil effects, local or general, followed the injections, they might weigh heavily against their use. But the writer is able to say that in no case, either in hospital or in private practise, has he seen any drawback beyond the slight feverish disturbance he has already described; and in private cases, when he has advised this treatment and left it to the practitioner in charge to carry it out, he has heard of no mishap of any kind, although he has always made inquiries.

#### A CASE OF POISONING BY JABORANDI.

Before the Society of Therapeutists of Paris on April 28 LAVAL recorded a case of a woman, suffering from chronic iritis, to whom was given thirty grains of jaborandi on one day for the purpose of producing profuse salivation and perspiration. As this dose did not produce the desired effect, a dose of sixty grains was given on the next day without marked influence. On the third day the patient obtained the larger dose of jaborandi from another druggist, and passed

into a very marked sweat after the ingestion of the infusion. The treatment was continued on the fourth, fifth and sixth days. At this time the patient began to suffer from palpitation of the heart, nausea, great anorexia, and a sensation as if a foreign body was in the throat. There was also a sensation of thoracic constriction. An examination of the throat showed it to be dry and red. In the treatment of conditions of the eye and ear in which jaborandi is thought to be useful, it is probably better to administer the alkaloid pilocarpine hypodermically rather than to employ the infusion.

#### OBSERVATIONS ON THE ANTICIPATION OF POST-PARTUM HEMORRHAGE, WITH REMARKS ON THE ACTION OF ERGOT ON PREGNANT WOMEN.

This important topic is discussed by WALKER in the *British Medical Journal* of March 6, 1897. Finally we may say in regard to his views that they are when summed up as follows, at least so far as the action of ergot in combination with strychnine, which is the formula the author usually adopts, is concerned:

1. That when administered previous to the termination of pregnancy in the case of women in whom a tendency to post-partum hemorrhage is known to exist, it tends in a marked manner to prevent the occurrence of hemorrhage.

2. That when so administered in ordinary doses, it does not produce any injurious effect on either mother or child, and that its exhibition seems to delay the commencement of labor in such case.

3. It tends to make the involution of the uterus more perfect, and lessens the chance of the occurrence of subsequent uterine troubles, many of which depend for their cause on imperfect involution of that organ.

4. It will not bring on premature labor or induce abortion unless uterine action has previously been set going.

5. In cases of threatened abortion its administration frequently seems to act as a uterine tonic, and in some cases tends to avert the danger of a miscarriage, provided the ovum be not blighted.

6. That if the ovum be blighted, and specially if it be detached, ergot usually hastens its expulsion.

Since writing the foregoing the writer has observed in the *Epitome* which appears in the *British Medical Journal* of January 16

an abstract of a communication made by Professor Schwab on the efficacy of quinine as an oxytocic. This drug, he maintains, "stimulates the uterine fibers when once they have begun to contract of their own accord. Like ergot, it does not set contractions going." The writer has never administered quinine as an oxytocic during labor, but it will be remembered that he has stated at the commencement that it was the unexpected immunity from post-partum hemorrhage in a patient to whom he had administered quinine prior to labor that induced him to carry out the preventive treatment he now advocates, and that it was quinine he first administered for this purpose. His observations, therefore, tend to confirm the views enunciated by Schwab as to the action of quinine on the uterine fibers, and further observations of the action of quinine as an oxytocic should be made. He does not think, however, that it would prove as reliable a drug for this purpose as ergot is. Schwab, too, confirms the opinion he has long held, that ergot does not originate uterine action.

---

#### THE USE OF ARTIFICIAL SERUM INJECTIONS IN MENTAL AND NERVOUS DISEASES.

MAIRET and VIREs are quoted in the *Revue de Thérapeutique* of March 15, 1897, as recommending these injections in epilepsy and mental diseases, for they may do good and cannot do harm. Furthermore, in certain cases it is justifiable to add to the saline solution such drugs as bromide of potassium, ergotin, and phosphoric acid.

---

#### IDIOSYNCRASY TO CAFFEINE.

In the *Revue de Thérapeutique* of April 1, 1897, DALCHÉ reports a case of peculiar susceptibility to caffeine. The patient was a diabetic sixty years of age, who had suffered from secondary grippe pneumonia. He received four doses of five grains of caffeine each. Immediately after this he developed marked excitement, great loquacity, delirium, vomiting, cutaneous hyperesthesia, and the development of diabetic coma seemed imminent, particularly as the reddish-brown reaction with the perchloride of iron was obtained in the urine. After a short time, however, the patient rapidly improved. The author is inclined to believe that the patient had an idiosyncrasy to the drug rather than that his disease made him unduly susceptible to it;

and in the discussion which followed Bardet mentioned a case in which a single drop of laudanum produced grave intoxication. Other cases have been known to follow the administration of the iodides, the bromides, and codeine.

Another reporter cited a case in which a young woman was seized with violent vomiting after being rubbed with a lotion containing laudanum; another case was seized with epistaxis whenever bicarbonate of sodium was taken in a little water; and in still another case the patient could not take nitrous oxide gas without the development of disagreeable symptoms.

---

#### THE USE OF SCOPOLAMINE.

TOMASSINI records in *La Riforma Medica*, No. 12, 1897, that  $\frac{1}{100}$  of a grain of scopolamine is beneficial as a cerebral depressant in cases of meningeal insanity. If given in injections it does not produce much pain or local reaction. Sleep comes on rapidly, the patient being quiet in a very few minutes. The pulse is regular, being little diminished in force or frequency; respiration is not altered. Sleep usually lasts from four to five hours, and may be prolonged to eight hours without any interruption. The cases in which scopolamine is particularly indicated are those in which a powerful sedative is required, as for example acute mania and maniacal epilepsy.

---

#### THE USE OF THE HOT PACK IN THE TREATMENT OF THE INSOMNIA OF NEURASTHENIA.

In the *Revue de Thérapeutique* of March 15, 1897, D'AULNAY points out the valuable results which are to be obtained in producing sleep in neurasthenia by means of the hot pack. The patient is first sponged off with cool water and is then quickly wrapped in a blanket which has been wrung out of hot water. Outside of this is placed a dry blanket, and about this dry blanket is also placed hot bottles. The patient in the course of a few minutes breaks out into a sweat, and after this sweat has been continued for five or ten minutes he is placed between warm blankets, rubbed off with a towel, and soon goes to sleep. In this article the writer records a number of cases of nervous insomnia in which this treatment produced very good results. It is not very much trouble, particularly if the trained nurse can administer it.

*THE TREATMENT OF MUCO-MEMBRANOUS ENTERITIS IN INFANTS.*

COMBY in the *Revue de Thérapeutique* of April 1, 1897, directs that in the treatment of this condition we shall combat the tendency to adynamia and collapse which is frequently present. If necessary we should administer saline injections. Carefully sterilized food should be employed, and different things should be tried until that most satisfactory to the child is discovered. Very often the following prescription in this condition will be found of value:

- ℞ Bicarbonate of sodium,  
Calcined magnesia, of each 5 grains;  
Powdered nux vomica,  $\frac{1}{4}$  grain.

This may be given to the patient two or three times a day according to the age. If constipation is a prominent symptom glycerin suppositories or small injections of glycerin made with a small syringe will be of value.

*A CASE OF POISONING BY POWDERED PYRETHRUM.*

FERRAND has recently reported to the Society of Therapeutists of Paris the case of a child of eleven months who took a considerable quantity of pyrethrum powder. Pallor, vomiting, collapse, slow and feeble heart, and depression of respiration asserted themselves, but the patient was saved by the administration of an emetic dose of ipecac. In some cases in which pyrethrum powder has been inhaled it has produced asphyxia by causing a spasm of the upper respiratory tract.—*Revue de Thérapeutique*, March 15, 1897.

*THE TREATMENT OF CHLOROSIS.*

In the *Revue de Thérapeutique Médico-Chirurgicale* is a paper by HUCHARD upon the treatment of chlorosis. He points out that these chlorotic cases can be divided into three classes: Those in which iron is absolutely useless; those in which it is fairly valuable; and those in which it is an absolute necessity. The cases in which it is useless are those which have been deprived of fresh air and sunshine, and only need proper food and outdoor life, with stimulant treatment, to regain their health. Those in which it is moderately valuable are the pseudo-chlorotics who have as an underlying cause a tendency to develop tuberculosis with general debility; but as a rule the more dyspeptic the patient the less good will iron do. The cases in which the iron is most useful are those in

which the patients are devoid of dyspeptic symptoms, when any one of the common iron preparations may be given in large or small doses with advantage. Should there be a syphilitic dyscrasia underlying the anemia, mercurials should be administered in addition to the iron, preferably the bichloride of mercury.

*THE TREATMENT OF THE VOMITING OF PREGNANCY BY OXYGEN WATER.*

The *Journal des Praticiens* of March 20, 1897, quotes GALLOIS as having employed oxygen water with very great success in the treatment of the vomiting of pregnancy. He has often found inhalations of oxygen useful. The oxygen water which he employs contains ten volumes of the gas, and is administered in the dose of one teaspoonful to the ounce, diluted with an equal quantity of water; or in other cases diluted even further than this. The liquid is to be taken in small quantities, half to one teaspoonful at a time. He claims that its action is rapid and that relief is soon obtained.

*THE TREATMENT OF WHOOPING-COUGH.*

In *La Médecine Moderne* of March 3, 1897, a quotation is made from a Russian journal in which the following methods of treating whooping-cough are advised: In some cases it was found that oxide of zinc in small doses with small doses of belladonna diminished the number and intensity of the attacks, but the cases lasted from eight to eleven weeks. Out of twenty-five children treated with oxide of zinc two succumbed to bronchopneumonia. The author is therefore not inclined to regard the oxide as a specific in whooping-cough. In fifteen children from two to five years who received terpine hydrate in full doses, the duration of the affection was seven to ten weeks. He considers that the terpine is particularly indicated in those cases with bronchopneumonia. The bromide of sodium was prescribed in five cases in children from two to six years in the dose of forty-five grains to one drachm in a day. These cases lasted from seven to nine weeks. In eight cases antipyrin was given to children varying from three to six years. The dose was large—from thirty to forty-five grains—and the attacks were not very materially diminished. In other cases antipyrin and codeine were combined, and in fifteen of these cases the duration was from six to eleven weeks. In five cases the author used sprays of cor-

rosive sublimate in the proportion of 1 to 1000 in the pharynx, with the result that the treatment extended only over three weeks. DITEL, the reporter, concludes that during the convalescent period of the cough the bromides are the best treatment, and that they may be gradually replaced by codeine; that if fever is present antipyrin is indicated, and if bronchitis is marked terebine is useful. He concludes that there is no specific medication, and that our treatment must be purely symptomatic.

#### *A CASE OF POISONING WITH ARSENIC INTRODUCED INTO THE VAGINA.*

*Treatment of May 13, 1897*, abstracts from the *Wiener Klinische Wochenschrift* of March 4, 1897, the following interesting case. It was that of a servant girl, twenty-five years old, who committed suicide by introducing white arsenic into her vagina.

At the post-mortem examination, besides the typical signs of arsenic poisoning in the internal organs, the following interesting conditions in the genital organs were found:

Large labia much swollen, edematous; on them and in their neighborhood numerous small round pustules, surrounded by an inflammatory halo, some of them dried up; much excoriation about anus and buttocks. Inner surfaces of large and small labia much swollen, dusky red, covered with croupous exudation. Hymen destroyed. Lower half of vagina permeable; two inches above the vaginal orifice a mass of pale-yellow fibrinous exudation, which occluded the vagina perfectly; the whole upper half of the vagina lined with pseudo-membrane, one-third of an inch thick, which also covered the fornix, the vaginal portion of the uterus, and the cervical canal. Exudation firmly adherent to the immensely swollen mucous membrane, which was thrown up in thick folds of a vivid red color, and closed in round a plug of crumpled-up yellow paper, the size of a cobnut, which contained a great quantity of white, opaque granules; the mucous membrane of the lower half was covered by a thin membranous exudation; the rectovaginal septum swollen, brawny, infiltrated to the thickness of nearly one inch, and containing numerous ecchymoses. Anterior half of rectum for about two inches dark brown, infiltrated, its mucous membrane covered with bran-like flakes of fibrin.

The quantity of white arsenic found in the vagina amounted to nearly six grains; in the

internal organs the analyst found half a grain of arsenious acid.

Deceased had not been pregnant. Only five cases of poisoning with arsenic from the vagina are on record.

#### *THE DIAGNOSIS AND TREATMENT OF ACUTE RHEUMATISM IN CHILDREN.*

M. B. CHEADLE, in *Treatment of May 13, 1897*, asserts that as in the rheumatism of children all the symptoms, both articular and constitutional, are usually subdued and sub-acute, active treatment by full doses of salicylate of soda is not usually required. The free exhibition of it is indeed often harmful by its depressing effect; children bear drastic treatment badly. When, however, the joint trouble and pyrexia are marked, the salicylate should be given in appropriate doses at short intervals until these subside. The milder drug salicin may in most cases be substituted for salicylate of sodium, given in doses of five to twenty grains; or quinine in doses of one to three grains every four hours. In each case an alkali, such as citrate of soda or potash, in full doses, should be combined—doses of five to twenty grains according to age. The use of depressant drugs, such as antipyrin, antifebrin, aconite, with a view to lowering temperature, cannot be too strongly deprecated.

The general evidence of statistics seems to favor the conclusion that cardiac inflammation is less frequent and less pronounced under full alkaline treatment than under any other. In the case of children this assumes special importance; the one great object of treatment should be to minimize this danger as far as possible. Whenever there is a suspicion of rheumatic inflammation, absolute rest in bed should be enforced, even if there is no sign of any affection of the heart. Complete physical repose and external warmth are essential.

The condition of slight rheumatism, in the case of children at all events, is treated far too lightly. Timely care in avoidance of fresh chill, of all excitement or strain of heart structures, may make all the difference in the degree of heart mischief remaining in the end. Dr. Sibson found that in acute rheumatism patients treated by rest escaped permanent heart lesion in the proportion of two to one, as compared with those allowed free action. When pericarditis supervenes, if there is much pain and distress, one or two leeches may be applied to the præcordia;

but anything like profuse extraction of blood is positively harmful. Children do not bear much loss of blood. The most effective local application is that of the ice-bag advocated by Dr. Lees. In pleurisy and pericarditis, where the inflamed membrane lies near the surface, and in intimate vascular connection with it, the application of ice appears not only to relieve pain but to exercise a favorable influence on the inflammatory process. It is usually grateful and readily accepted even by young children.

In cases of the deadly form of cardiac inflammation, which is perhaps the most characteristic feature of the rheumatism of childhood—viz., persistent, recurrent, subacute endocarditis and pericarditis—opium, digitalis, and strophanthus, with an alkali, are the drugs of most service. The former is best given as nepenthe in frequent small doses of from one to five drops, according to age, every four hours; and it does more than any other drug to relieve distress, lessen dyspnea, and subdue pain. If given with proper care it is perfectly safe.

Alcohol is also a most useful agent, as much from its sedative as by its stimulant property.

As a last resource, and in the case of older children only, when the heart shows signal signs of failure, when the first sound becomes short and feeble, and the pulse small and irregular, hypodermic injections of Liquor Strychniæ (B. P.) in doses of one-eighth drop to one drop or more, according to age—combined with five to ten minims of brandy—or one to three minims of digitalis, given in the same way, afford the most powerful means of resting the flagging heart. Usually, however, this only effects a brief rally and respite from the final collapse.

#### THE TREATMENT OF SOME FORMS OF HEMIPLEGIA.

LEONARD G. GUTHRIE, in *Treatment* for May 13, 1897, in discussing this subject points out that the actual treatment is largely based on prognosis—that is to say, on our knowledge of the course most likely to be pursued.

Thus, as the leg recovers before the arm, and its recovery is most important to the patient, we devote attention to it first. As joint movements return from above downwards in order, we treat joints in this order, so as to encourage the patient by the success which attends treatment of each in turn.

Passive movements are necessary from the

first in order to prevent adhesive rigidity, which should never be allowed to occur at all.

Massage and electricity improve the general nutrition of the limbs. Artificial warmth is essential. Pine-wool coverings serve this purpose.

Galvanism is mostly useful. The strength of current should not exceed five milliampères, which, roughly speaking, requires from fifteen to twenty cells. The negative pole should be stabile, the positive mobile.

Faradism is contraindicated when spasticity is present, but is useful in flaccid cases. The primary current should as a rule be employed.

The patient should be encouraged to make the most of each return of power as it occurs. This is the most important part of the treatment.

Mechanical contrivances, such as elastic bands of increasing thickness, to be passed over adjoining fingers, and stretched by separating the fingers, and india-rubber balls gradually inflated to be compressed within the hand, are useful in flaccid cases. The patient should occupy himself in kneading and moving the fingers of the affected hand with the other.

Disordered association may be relieved by training. In teaching the patient to walk, the words "right," "left," should be uttered as advance of each limb is required. A sharp tap behind the affected knee at the proper time will sometimes relax spasm, and enable the leg to be brought forward. An elastic accumulator fixed above the knee and carried round the neck is of similar service. Dorsiflexion of the foot may be improved by appropriate exercises.

In conclusion, it is the non-recognition of functional conditions preventing recoveries from hemiplegia which brings discredit on the profession. Such cases swell the roll of miracles at the shrines of Bernadette and Winifride. Similar miracles may equally well occur at any physician's shrine.

#### TREATMENT OF CYSTITIS IN THE FEMALE.

In the *Polyclinic* of May 22, 1897, BLOOM tells us that in the treatment of cystitis, if acute, we should put the patient to bed at once. This is the first essential in the management of such a condition. The diet should be light and unstimulating—fluid, milk, broths, and eggs. Avoid all stimulants; keep the

bowels freely open with salines; keep the patient warmly clad. If the urine is acid, it should be rendered neutral by alkaline drinks such as Vichy water with plenty of soda in it, as well as by any of the prescriptions mentioned previously.

In nearly all these cases the water is alkaline, though not as frequently in acute as in chronic cystitis. The best agent for neutralizing an alkaline urine is benzoic acid, either in solution well diluted with water, or in five-grain capsules, which are preferable, every three hours until the desired effect is obtained. Use large draughts of water after each capsule. Salol, in five-grain capsules every two hours, until the water is acid, is most valuable where there is much ammoniacal decomposition.

Boric acid ten to twenty grains in cinnamon water every three hours soon corrects offensive urine. For pain, which is often a prominent symptom, there seems to be nothing better than five-grain doses of acetanilid repeated as indicated.

Irrigation of the bladder becomes a most important adjunct in the successful management of these cases; of course, if it is acute cystitis, not until after the acute symptoms have subsided. One of the best irrigations for this purpose is potassium permanganate in one-twelfth- to one-fourth-per-cent. solution. Another very good one is one-half-per-cent. solution of acetanilid. In chronic cystitis this is one of the most valuable solutions that can be used. It can be increased in strength if found necessary.

The technique of vesical irrigation is most important. The apparatus is very simple, consisting of a soft rubber catheter joined to a piece of rubber tubing by a short piece of glass tube. A small glass funnel is connected with the other end of the rubber tube. The whole apparatus can be from four to five feet long.

Sterilization is most important before using it and immediately afterwards. Upon thorough cleanliness depends largely the successful issue of the case. Asepsis and antisepsis are as important in this operation as they would be were one about to open the abdomen. After carefully cleansing the meatus urinarius as well as its immediate surroundings, the catheter, well lubricated with sterilized vaselin, is introduced, the urine drawn off while the instrument is still in place, and the tubing filled with the column of urine, thus preventing the entrance of air; the funnel is filled with the irrigating solution and gradually

raised, distending the bladder slowly. The quantity used will depend upon the vesical irritability. Some bladders will not tolerate over an ounce; the maximum quantity should not exceed five ounces. The funnel is then lowered and the bladder evacuated in the same careful manner.

This procedure is repeated till the washings come away perfectly clear and clean. The temperature of the solution should be about 100° or 105° F.

We use this once a day at first, or at most twice a day, and after a few days lessen the frequency. Even this may fail in certain bladders to cure the trouble; then one will have recourse to drainage, keeping the bladder empty by a self-retaining catheter. This is proceeded to by first dilating the urethra to the point of paralyzing the vesical sphincter.

If this fails, Emmet's operation becomes necessary for draining the bladder through the formation of a vesico-vaginal fistula.

If the vesical irritability is due to caruncle, the only permanent relief is total extirpation under careful antiseptic precautions. If due to fissure, or ulcer, dilatations of urethra, curettage, and the application of carbolic acid or silver nitrate, always being careful to draw the water through a sterilized catheter for several days, will meet with success.

In the treatment of gonorrheal vesical irritability nothing seems to do more good than the application of pure ichthyol to the urethra after carefully cleansing it with a solution of mercury bichloride, and giving internally a capsule of two grains of ichthyol and five minims of oil of sandalwood every three hours, and one or the other of the prescriptions mentioned.

In chronic cystitis it is important to look after the general health, as well as the local treatment, and if it is, as is often found, associated with a retroversion, the success will be very much greater if the uterus is restored to its normal position.

---

#### *SOME RECENT SUGGESTIONS IN THE TREATMENT OF EPILEPSY.*

Since the introduction of potassium bromide in the treatment of epilepsy by Sir Charles Locock in 1857, no agent has been found so generally useful. It is admitted, however, that the bromide treatment leaves much to be desired, and therefore new remedies are brought forward continually with the hope that they may prove more efficacious

in controlling the paroxysms, and at the same time less active in producing untoward symptoms. It has been clearly shown that certain bromide preparations have a less deleterious effect on general nutrition than others, though the same salts may be, to some extent, less powerful; this is particularly true of strontium bromide, which is far less apt to induce acne, mental depression, and gastric disturbance than the corresponding salts of potassium. According to Wood, both ammonium and strontium are stimulants to the circulation, while potassium is a powerful depressant. The strontium salt differs from the ammonium salt in being directly less active as a bromide, but in having a more happy effect on the alimentary canal. As the cost of the strontium salt has been lately considerably reduced, its employment in epilepsy will doubtless become more general. Within the last few years three drugs have been introduced in the treatment of epilepsy, which, though of little value, when administered independently are very useful adjuvants, and when combined with a bromide often lessen materially the amount of the latter required to control the seizures. These three remedies are antipyrin, the fluid extract of *Solanum Carolinense*, and opium. Antipyrin, in doses of ten or fifteen grains a day, can be given with ammonium or strontium bromide for several months without ill effects. In some instances, however, its prolonged use excites circulatory disturbances, such as coldness of the extremities, cyanosis, and copious perspiration. *Solanum Carolinense*, or horse-nettle, was first recommended by Napier. Potts (THERAPEUTIC GAZETTE, December 10, 1895) draws the following conclusions from the use of this drug in seventeen cases of epilepsy: That the drug has a decided influence for good upon the epileptic paroxysm; that this influence is probably not so great or so sure as that obtained by the use of antipyrin and the bromide salts, or even of the mixed bromides; that in those cases in which it is of service it relieves the paroxysms without causing unpleasant symptoms, such as are sometimes caused by the use of large doses of the bromides; that the dose ordinarily recommended (ten to fifteen drops of fluid extract) is too small, and that as much as a teaspoonful or more four times daily is often needed to secure results.

In the *Neurologische Centralblatt* of November 7, 1893, Flechsig announced that he had obtained brilliant results in epilepsy by prefacing the bromide treatment with the ad-

ministration of opium in ascending doses. His method consists in exhibiting the extract of opium for six weeks, in doses rapidly increased from a quarter of a grain to five grains three times a day, when the drug is stopped, and half a drachm of potassium bromide three times a day is substituted; these large doses are continued for one month, and then gradually diminished until about thirty grains per day are being taken. This treatment has been quite thoroughly tested, and most observers agree that it is of decided advantage in certain cases.

Collins, who employed it in fifty cases, has drawn the following conclusions: The plan suggested by Flechsig, if not a specific in the treatment of epilepsy, in almost every case in which it has been tried there has been a cessation of the fits for a longer or shorter time; a relapse generally occurs in a period varying from a few weeks to a few months; the frequency of the fits after the exhibition of the opium is, for the first year at least, lessened more than one-half; the attacks occurring after the relapse are much less severe in character than those the patient has been accustomed to having. This plan of treatment is particularly valuable in ancient and intractable cases; in recent cases of idiopathic epilepsy it cannot be recommended. It is an important adjuvant to the bromide plan as ordinarily employed; the opium acts symptomatically and merely prepares the way for and enhances the activity of the bromides and other therapeutic measures. This treatment permits the use of any other substances known to have a beneficial action in epilepsy.

Sulphonal and trional are unquestionably of value, and occasionally succeed where the bromides fail. While the danger of chronic poisoning precludes their prolonged use, they may be prescribed with advantage when a temporary change of treatment is for any reason desirable.

In a certain proportion of cases the exciting cause of the paroxysms seems to be the absorption of toxic substances from the intestine, resulting from indigestion and constipation. This factor of autointoxication has been carefully studied by Herter and Smith (*New York Medical Journal*, August and September, 1892), who studied 238 specimens of urine from thirty-one epileptics. In seventy-two per cent. of the observations there was an unmistakable evidence of intestinal putrefaction, as indicated by the presence of ethereal sulphates in the urine in large quantities, just before the occurrence of the

paroxysm. Such cases are remarkably benefited by regulation of diet, the use of alkaline laxatives, and a course of intestinal antiseptics.

As regards the diet, recent investigations confirm the belief that most epileptics do best on a diet that is chiefly vegetable. Merson (*Dietetic and Hygienic Gazette*, March, 1892) has recorded the results of a series of observations on twenty-four chronic epileptics. Twelve of the patients were put on nitrogenous and the other twelve on farinaceous food, and this arrangement was continued for four weeks; when the diet was reversed, and observations continued for another period of four weeks. Out of the twenty-four cases there was, in fourteen, a decided decrease in the number of fits during the period of farinaceous diet; the average number of seizures for the farinaceous period was 10.7, as compared with 28.3 for the nitrogenous period. The same results were obtained by Short (*British Medical Journal*, May 18, 1895) in the treatment of fifty epileptic women who had previously been carefully observed for twelve months in order to ascertain the average number of fits.

The hope that surgical intervention might prove of great value in epilepsy has not been realized, and a more careful study of the cases subjected to operation has proved that this method of treatment has but a very limited field of usefulness. The two classes of cases in which operations have been performed are those resulting from reflex irritation and those dependent upon some focal brain lesion. It has been shown, however, that reflex epilepsy is very rare, the proportion of cases resulting from some peripheral irritation not exceeding one or two in a thousand; and that, moreover, there are very few cases recorded in which the removal of a supposed local irritation has succeeded in permanently checking the convulsions. In the few cases of epilepsy resulting from brain injury the epileptic habit has been, as a rule, so firmly established that an operation rarely cures, and only seldom diminishes the frequency of the attacks.

Mason (*Medical News*, March 21, 1896) has tabulated seventy cases of trephining for epilepsy, and of this number three died from the operation, three were cured, and four were improved. If trephining and ablation of morbid tissue were reserved for cases in which the injury was received only a few months prior to the development of the

epilepsy, the proportion of cures would doubtless be larger than is indicated in Mason's statistics.—*University Medical Magazine*, May, 1897.

#### SPRAINS AND THEIR TREATMENT.

DOUGLAS GRAHAM (*Boston Medical and Surgical Journal*, June 24, 1897) says an eminent surgeon once remarked to him, "What you do, doctor, with your massage and movements, is to cure the patients of the results of our treatment." The customary treatment of sprains and its results are well known—absolute rest in a fixed dressing, resulting often in recovery, but too frequently in stiff, weak, and irritable joints. Sometimes these joints are deliberately sprained over again by the surgeon, with a view to loosening adhesions and overcoming the stiffness. But, unfortunately, this plan may cause the adhesions to reform stronger than ever.

A form of treatment that is no doubt well adapted for sprains of slight or moderate severity of the outer aspects of the ankle has recently been revived by Dr. V. P. Gibney, of New York. It is strapping with strips of rubber plaster alternately at right angles to each other over the outer and lower third of the leg, ankle, and foot. Elevation of the foot over night or for a few hours, and immediate massage, are advised as good preliminary measures before applying the plaster. This treatment is said to involve no loss of time, to require no crutches, and not to be attended with any ultimate impairment of motion. This plan of strapping sprained ankles with adhesive plaster was used with brilliant success by Dr. Hood fifty years ago.

If the patient is wearing a well-fitting boot at the time of spraining foot or ankle, let him keep it on and walk about moderately. If the boot is not quickly snug by reason of the swelling, it should be laced tighter. The author has twice walked off a mild sprain in this way himself. The pressure of the leather and the motion of walking give a sort of automatic massage. And when we think of it, this is not so very wonderful after all, for it is safe and salutary in sprains to allow motion that does not cause pain. It is unnatural motion that has caused injury, and even after this natural motion can often be immediately indulged in to a greater extent than either physician or patient take the trouble to find out.

A plan of treatment that seems to be well suited to sprains of all degrees of severity, and which can be used with or without fixed

dressings and bandages, according to the indications, is massage properly applied. Massage should not be begun immediately over a recently injured joint; neither should passive nor active motion be encouraged in spite of pain caused thereby, whatever others may say to the contrary. After a recent injury, pain is the cry of Nature for rest to allow repair. And it is quite possible in sprain, and even in fractures without displacements, to keep the injured parts at rest while the surrounding tissues are preserved in health and activity, the circulation kept active and absorption hastened, by means of massage.

A snug bandage is usually sufficient to afford rest and support, and to press the swelling out in the intervals between the massages. But if the bandage does not give sufficient support, then an easily removable splint or plaster may be applied. Joints tender and swollen, that do not admit of massage being applied directly upon them, can be approached by commencing on the healthy tissues some distance above them and nearer to the trunk, by gentle stroking in the direction of the returning currents of lymph and blood, and gradually proceeding downwards. The healthy tissues beyond the seat of the injury should also be similarly treated, as the circulation is hindered in getting to and from them by reason of the swelling. Besides the soothing effect of this, which enables one to gradually encroach upon painful parts, the returning currents are pushed along more rapidly, making room for exudations to be carried off. For this purpose each hand should make alternate strokes, using the greatest possible extent of the palmar surface whilst the limb is in a comfortable position.

After working a few minutes in this manner, deep manipulation, or massage properly so-called, may be brought into play, beginning as before above the painful joint by adapting the greatest possible extent of hand and fingers, one hand contracting and making the greatest push upwards as the other relaxes while gradually approaching the objective point. The effect of this is agreeably benumbing or analgesic, lessening pain without decreasing ordinary sensations, besides pushing along the deeper circulation more vigorously. The parts beyond the sprain should be treated likewise. By alternately stroking and kneading in this manner we can soon make gentle, firm pressure over the but recently painful and swollen joint. If sufficient tact be used this pressure may not hurt, but be positively agreeable; and very soon it

can have motion added to it, thus constituting massage by which the effusion and exudation are spread over greater surfaces and brought into more points of contact with veins and lymphatics, absorption by which is materially aided by the pressure of massage.

It should not be forgotten that when a light touch is disagreeable, firm pressure often affords relief, so that the whole hand is better than the finger-tips where it can be used for massage. Recent periarticular exudations are thus speedily dispersed and absorbed, which might in time have become organized, while superabundance of intra-capsular fluid is pressed into the absorbents, the function of which within the joint is increased by the pressure from without and by the acceleration of their current from the massage above the joint.

In recent sprains and synovitis this method is rational, for it quickly relieves the heat, the pain, and the swelling, and takes the pressure off the nerve filaments. The comfort to a joint, even after a single sitting, cannot be believed unless felt. The good effects of the massage are continued by means of a bandage well applied; but the pressure of a bandage alone, though it affords support, hinders the circulation by its continuous pressure, and will not take the place of massage, which when rightly applied is an intermittent pressure and an aid to the circulation.

KRASKE has demonstrated that the application of a rubber bandage to the leg of a rabbit for six hours has produced hyaline degeneration of the muscles, from which they do not recover. If we want weak and atrophic muscles, let the bandage be continued after the swelling has disappeared. Rubber bandages the author would not advise except for temporary use, as when a patient with weak joint wants to go sea-bathing. They are intensely disagreeable on account of the smell of the rubber combined with the perspiration which they produce. They are dangerous by literally strangling the tissues, for each turn, by its elastic tension, represents much more compression than the force used in putting on. Often the author has taken them off and applied a domett (or cotton flannel) bandage, and always to the great delight and comfort of the patient. A domett bandage is firm, soft, warm, and comfortable; and when you have put one on, you know what you have done, and a few extra layers of this will often take the place of splint and plaster.

Some careful physicians who are in favor

of massage in sprains think it well to wait a few days while using hot and cold water or some other treatment before beginning massage. In this event the author is not sure that the effects of massage are not more striking in arousing the limb from the lethargy and stupor into which it has been plunged by the shock of the accident. When this local lethargy and stupor have been prolonged for a month or six weeks, as must necessarily be the case when a limb is done up for a fracture, the immediate effects of massage in bringing the limb back from death to life, in starting anew the circulation, in awaking sensation and motion, are often remarkable. But sometimes, under a plaster-of-Paris dressing, the connective tissue proliferates and assumes a plank-like hardness, a literal deadness, that is most discouraging to an intelligent masseur and which is a sure sign of tedious recovery. The author believes it is possible to prevent this by having the cast removed occasionally and the limb masséed without disturbing the fragments. Rest is necessary to produce ankylosis, and he does not see the need of allowing well joints to be imprisoned to such an extent that they will become stiff while a fracture above or below them is uniting, when a little precaution in the way of massage and passive motion might preserve the function of the limbs.

From the foregoing the following conclusions would seem to be justifiable:

A sprain is a wrench or twist of a joint—a sudden partial displacement of two articulating joint-surfaces, followed by immediate replacement.

The symptoms are pain, swelling, discoloration, and usually heat, with impaired motion.

Its diagnosis may be obscured by the swelling, which may conceal a fracture underneath.

Whatever will quickly reduce the heat, the pain, and the swelling—such as massage, snug bandaging, and elevated position of the joint—will proportionately make the diagnosis easier.

The means just mentioned are therefore not only valuable for diagnosis but also for treatment; and their use in many cases of sprains of all degrees of severity shows that they recover in one-third of the time that they require under absolute rest and fixed dressings without massage.

Even a sprain of a joint previously weakened by malignant disease may be rapidly ameliorated by massage, and useful motion gained before amputation.

### PRIAPISM.

Dr. R. W. TAYLOR, of New York, read a paper on this subject before the American Association of Genito-Urinary Surgeons at its meeting in May last (*Journal of Cutaneous and Genito-Urinary Diseases*, July, 1897). He stated that this affection may be divided into the following classes:

1. Priapism observed in infants and children, induced by reflex action, in cases of long, tight, adherent prepuce, of stone in the bladder or prostatic urethra, and of worms in the rectum.

2. Priapism in adult subject, symptomatic of stone in the bladder, stone in the prostatic urethra, stricture, cystitis, and observed during retention. In these cases the uneasy or painful sensation is felt in the glans penis, while the body of the organ usually is only moderately congested and sometimes curved downward or laterally. This condition disappears upon the removal of the cause.

3. Priapism symptomatic of gonorrhea, with perhaps involvement of the corpus spongiosum and downward curvature. This condition is painful and transitory, and may occur several times during the night. In cases of downward curvature of the penis due to inflammatory engorgement of the corpus spongiosum and spasm of the musculature of the urethra, the term chordee is applied.

4. Priapism due to the ingestion of cantharides, which is a form that is seldom or never seen now, since this drug is so rarely used in medicine.

#### 5. Essential priapism.

The latter form, which was the only one considered by the author, may be divided into four varieties: (a) Priapism caused by injury to the spinal cord (either high up or low down) and by blows or violence inflicted upon the perineum; (b) priapism which is a symptom of cerebral or descending spinal-cord disease; (c) priapism which occurs after alcoholic and sexual excesses; and (d) priapism which comes on a person in ill health, in whom it is difficult to obtain data as to local injury and causation, and in which cases there is now a tendency to look upon leucemia as the etiological factor.

Few definite statements can be made as to the prognosis of priapism of any form. In those cases in which injury to the corpora cavernosa or thromboses can be made out, incisions may greatly expedite the cure. The existence of spinal disease necessitates a guarded prognosis. In very much run-down

neurasthenic subjects, in sexual perverts, and those suffering from leucemia, the chances are that the priapism will be very persistent, and relapses are apt to occur.

In the author's opinion nothing like a routine method can be laid down. This much, however, can be stated with emphasis: Chloroform narcosis has failed in every case in which it has been used; ice usually does more harm than good; electricity has no value and may even be harmful; and leeches to the number of sixteen and forty have failed to produce any amelioration in the condition of the penis, and have been injurious in their depletory effects.

The speaker said that his own preference in dealing with these cases is to resort early to moderate and tentative incisions into the most turgid part, or into parts which are the seat of continuous pain, or into nodular masses in all probability the result of traumatism. It is always good practise in priapism to use either the potassium salt alone or in combination with mercury, when a history of antecedent or present syphilis is elicited. A number of cases are on record in which the condition was relieved by potassium iodide. Bromide of potassium, chloral, belladonna, and morphine may be of benefit, especially during paroxysms. Hot baths, hot and cold spinal douches, sponging with hot water, spinal cauterization, anodyne poultices, and perhaps ice-bags, may be found beneficial, but the latter must be guardedly used. Any ephemeral or systematic disorder should receive appropriate treatment.

Dr. Taylor reported two cases illustrating the points made in his paper.

---

*A NEW METHOD OF REMOVING POLYPOID GROWTHS FROM THE BLADDER.*

GEORGE CHISMORE (*Journal of Cutaneous and Genito-Urinary Diseases*, July, 1897) publishes a method which he believes no one has hitherto undertaken to remove vesical polyp by. Although his experience is limited to the two cases here reported—purely accidental in the first, entirely intentional in the last—the immediate results (checking a dangerous hemorrhage and relieving an over-distended bladder) were so easily attained that, whether the cure proves permanent or not, he believes the procedure of sufficient value to bring it to attention and to recommend it for trial.

The principle on which the operation is

based is that of catching, by aid of the suction exerted by an aspirator attached to a litholapaxy catheter, or other suitable tube, the growth, or growths, in the eye of the instrument, when by gentle traction and slight to-and-fro movements they are torn from their attachments and drop into the reservoir of the wash-bottle.

To accomplish this he uses an ordinary curved litholapaxy tube, of available size, to empty the bladder, then couples on his evacuator, which is so shaped as to fit the hand and give one full control of the point of the catheter. He then injects two or three fluid-ounces of a borated solution as hot as can be borne, to which cocaine is added if needed to control the pain; then systematically go over the interior surface of the viscus with the point of the catheter, at the same time compressing and relaxing the bulb, trying by touch to locate the site of the growth. If the outflow is arrested when the point is in contact with the bladder-wall, the instrument is held stationary a few moments, the hand holding the bulb, regulating the amount of suction exerted, then gentle traction accompanied by a slight sawing motion is made.

If the occluding body be a polypus it will soon give way and quickly find its way into the reservoir. The author finds it easy to determine whether it be the healthy wall of the bladder that is caught or not, by the absence of the well-remembered thud and the evidence of pain that all who have done a litholapaxy will recall.

When a polypus is caught the check of the outflow is not nearly so abrupt; there is no expression of pain from the patient, the point of the occluded catheter is somewhat movable, and not apparently glued to a fixed spot; besides, in cases of pedunculated tumors the stoppage may take place while the eye is not nearly in contact with the bladder-wall. It is hard to convey in words the slight variations in the sense of touch, but he was astonished and delighted in his last case to observe how easily and clearly he located the site of the growths, and with what ease the tumors were brought away.

The writer supposed from his first case that the growth would have to be large enough to fill completely the eye of the catheter in order to make the suction effective; the second, however, clearly demonstrated that such was not the fact. There were many small polypi entirely too little to close the eye of the No. 25 F. catheter which he used. Either their bases must have been ses-

sile, several caught at once, or some alterations have taken place in the mucous coat from which they sprung that enabled the suction to exert sufficient power to drag them away.

For reasons that are obvious no estimate of the ultimate results of such an operation can be predicted, but it is contended that enough has been shown to make recourse to this simple and painless procedure justifiable in cases of emergency, where necessary time to remove a patient to hospital, or other preliminaries to more radical measures, are to be gained, particularly in those cases where the bladder is filled with clots, and retention from overdistention is present with its attendant suffering.

#### *A CASE OF TOTAL EXTIRPATION OF THE BLADDER.*

TUFFIER reports a case of total extirpation of the bladder, for an extensive tumor of that organ, followed by recovery.

The patient, a man forty years of age, had had urinary symptoms for three years, beginning with a sense of discomfort in the hypogastrium, which was soon followed by frequent and painful urination, which later became almost intolerable. Hematuria first appeared at the end of two years, since which time there have been abundant hemorrhages at irregular intervals. Patient's general condition was fairly good at the end of the first year.

On admission there was intense pain in the hypogastrium, radiating to the testicle. Suprapubic incision revealed a hard tumor with friable surface involving the walls of the entire left side of the bladder and the mucous membrane of the organ throughout. Free hemorrhage followed manipulation. The bladder was tamponed for twenty-four hours, and then drained for three weeks. The bladder was then extirpated. It was first tamponed with iodoform gauze. The abdominal incision was then lengthened, and it was further enlarged by a lateral incision on either side extending to the inguinal canal; the adhesions resulting from a former operation were broken down. The whole surface of the bladder was easily freed by the finger as far back as the points of entrance of the ureters. The bladder was then drawn upward through the wound, its neck was isolated by the finger, and the inferior vesical arteries and ureters were clamped and cut. The bladder being drawn high up through the

wound, it was possible to dissect off its peritoneal investment, and to free it thus from its attachments; after which it was removed. The clamps were then removed from the ureters. A catheter was introduced into each, and secured by a single suture passed through the wall of each ureter. The sutures were left long. A small incision was then made into the rectum on either side, and the ends of the ureters, together with their catheters, were led through these and out through the anus. The sutures were attached externally to a rod, to prevent their ulcerating into the rectum. The cavity left by the removal of the bladder was tamponed with iodoform gauze and the abdominal wound was closed except at its lower portion.

The tumor proved to be an alveolar epithelioma. The patient's condition was critical on the second day, but thereafter improved. The packing was removed on the third day. At this time the urine was normal in quantity. On the sixth day the urine flowed through the abdominal wound as well as through the catheters. These were removed on the following day, and siphon drainage was placed in the abdominal wound. There was a fecal discharge through the abdominal wound on the ninth day, which persisted for two days and then ceased. On the twenty-first day a phlebitis of the deep veins of the right leg occurred, but did not seriously retard the convalescence, which was uninterrupted from that time. In the sixth week the patient was up and about; and thereafter he was well and practically free from all symptoms.—*Boston Medical and Surgical Journal*, June 24, 1897.

#### *ADENOID VEGETATIONS.*

E. O. Sisson in *The Laryngoscope* for June, 1897, gives a careful *résumé* of the subject. In regard to the treatment each operator has his own favorite method, and each one undoubtedly possesses advantages. The author simply outlines briefly the steps in the operation he makes, and which has yielded him very satisfactory results. That vexed question as to whether an anesthetic should be given seems to have been about settled by the different authors, they having come to the conclusion that it is best in children to give one: First, because they are unmanageable to a greater or less extent without it, and a more thorough and satisfactory operation can be performed when it is used; second, the danger attending the giving of an anes-

thetic in children is slight, and complete anesthesia is never required. In individuals above puberty so many things arise to modify the question that the operator should exercise his own judgment as to whether a complete removal under an anesthetic or repeated sittings is desirable. Again, the position of the patient during the operation has provoked much discussion, some preferring the sitting, the same as for tonsillotomy; others the recumbent. The latter seems to the author to be the most desirable, for as soon as the operation is completed the patient's head is hanging over the table, and the blood is passing through the nose and mouth, thus avoiding all danger from its running down the trachea. When the child is anesthetized, and the mouth-gag inserted (preferably Denhard's), it is a question of a very few seconds to tear out the larger portion of the growth with the forceps. The author used Gradle's model, or Casselberry's. The former is the one adopted and highly recommended by such men as Mayer and Asch, and is used exclusively in all their adenectomies. After removing the large portion of the growth with the forceps, he followed up with a thorough curetting, using Gottstein's antero-posterior curette. The after-treatment is simple: some efficient and pleasant antiseptic should be used as a gargle and mouth-wash, and the patient kept on a liquid diet for a few days.

*CLINICAL NOTES ON A SIMPLE METHOD  
OF OPERATING ON VARICOSE VEINS  
OF THE LEG.*

ARTHUR E. BARKER (*Clinical Journal*, June 16, 1897) states that having for some time past adopted a method of operating on varicose veins of the leg which has given excellent results, although departing in a measure from the usual routine, it appears desirable to make a note of it in order that others may test it. Its chief merit consists in the fact that no foreign body is left in the wound in the shape of ligatures or sutures, and that it saves much time. The latter point is one of considerable importance, not only to the patient, who is thus saved any prolonged anesthesia, but to the surgeon, who nowadays is called on to do a very great many of these operations, both in hospital and private practise.

It goes without saying that the method is only proper where perfect asepsis can be secured. The leg is first washed, shaved, and carbolicized. Then the saphena vein is

exposed as high as possible in the thigh, preferably at the saphenic opening, as recommended by Trendelenburg, by incision of about two inches long. The vein is then caught above and below by two ordinary serrated Wells forceps, and a piece cut out between them. A sponge is then placed in the wound and the vein is similarly treated lower down in three or four places—*i.e.*, wherever markedly varicose. When all the wounds have been dried, and all bleeding stopped with catch forceps, the latter are removed one by one, and an ordinary white gauze bandage, which has been steeping in 1-to-20 carbolic lotion for forty-eight hours, is applied to the limb in the usual way well below the lowest wound, and is wound round until it is about to cross the lowest wound. The edges of the latter are held together with the left thumb and first finger, and the bandage is carried across them. When the fingers are removed the edges will be seen through the transparent bandage to be coapted very accurately. If this is not the case at one spot or another, a probe slipped under the bandage, through which the edges can be still well seen, will easily adjust the edges, while the gauze is held taut. Then the bandage is carried up the limb, each wound being similarly treated. Over the gauze the author usually lays a strip of salicylic wool, and retains it with firm turns of an ordinary bandage to keep steady, elastic pressure. This dressing is left on until the tenth day, when the wounds will be found to be closed by a linear scar as accurately as if they had been stitched, and only require a little wool and collodion for a few days longer.

The advantages of this method—which is only an application of that which Dr. Crédé of Dresden applies to amputation wounds—are its simplicity, its rapidity, and that the patient has no removal of stitches to look forward to. There is also the advantage that no ligature is left in the wound. Such ligatures occasionally, though rarely, give rise to pain for weeks.

The only point to be specially attended to is the arrest of hemorrhage from collateral vein branches as well as from the main trunk, and even pressure.

Those who become familiar with this method will, the author feels confident, never go back to the more elaborate ligaturing and suturing.

From the patients' point of view, too, there is a great gain, and when told the day after operation that there is nothing further to be

done to the wound except to remove the dressings, they are more than satisfied.

In some cases where patients are inclined to vomit after the anesthetic, a fine ligature may be applied to the upper end of the saphena vein, as the forcing of sickness may break the adhesion produced by the forceps. But such cases are rare, and firm bandaging meets them.

#### *SOME OF THE DIFFICULTIES OF CATHETERISM IN THE MALE.*

Dr. A. KOLLMAN has contributed an article on this subject to a *Festschrift für Benno Schmidt* recently published in Leipzig. An abstract of the article appears in the *Centralblatt für Chirurgie*. The author deals with the hindrances of catheterism under normal conditions of the urethra, with no impediment in the way of urination. He refers them to the pubic symphysis, the middle layer of the perineal fascia, the sinus of the bulb, the prostatic sinus with the prostatic ring, and the trigonum vesicæ of Lieutaud, the most important of which, he says, is the sinus of the bulb. Among the circumstances which may lead to difficulty at this point is unusual sensitiveness of the mucous membrane of the part, contact of the catheter with which gives rise to spasmodic constriction of the membranous portion of the urethra, constituting the spastic stricture of authors. A point of greater significance is the aptitude of the bulbous portion of the urethra with an abundance of folds; and another is an unusual distance between the sinus of the bulb and the entrance to the isthmus.

As regards the folds and pockets of the remainder of the anterior urethra, the author agrees with Dittel and Grunfeld that importance is to be attributed only to the pocket on the upper wall of the fossa navicularis, often connected with a Morgagnian lacuna, and to the little raphé of mucous membrane on the border of the Morgagnian crypts of the pars cavernosa. Occasionally the former is remarkably deep, so that the instrument may catch in it; the latter can hardly prove a hindrance unless a fine flexible instrument is used. The same is true of the excretory ducts of the acinus mucous glands. In the normal condition of the urethra they are minute depressions invisible to the naked eye; under the influence of gonorrhea, however, they may attain a notable size, but never to a size sufficient for

them to constitute an obstacle to the introduction of a rigid instrument. It was by urethroscopy, says the author, and especially by the observations of Oberlander, Neelson, and Finger, that the relations of the mucous glands of the urethra and the pockets and hollows partly connected with them have been made clear within the last few years.

Folds, pockets, and hollows of other sorts capable of hindering catheterism the author regards as very exceptional. He cites a case of Grunfeld's, in which there was an opening in the posterior wall of the urethra, situated about three inches from the external meatus, that led to a submucous passage an inch deep into which an instrument as large as that numbered fifteen on Charriere's scale could be inserted. He adds that a like instance has come under his own observation. On the lower wall of the urethra, in front of the bulb, there was a blind passage about half an inch deep, lined with urethral mucous membrane, and opening anteriorly, which ran parallel with the urethra and readily admitted a No. 23 catheter. He thinks that such diverticula are not to be looked upon as acquired, but as congenital.

In one instance Dr. Kollman has had the opportunity of observing a rudimentary pocket formation capable of constituting an impediment to catheterism, and of a kind that he has not found mentioned in endoscopic literature. This, too, he regards as a congenital formation corresponding in situation to the outlets of Cooper's glands, and the remark is made that in many dissections Henle saw the excretory ducts of these glands marked by little folds and pits. The author suggests that an examination with the urethroscope should not be begun at the bulb and carried forward toward the glans, but *vice versa*, to avoid overlooking certain pockets in consequence of closure of their entrances. He himself uses a special tube of his own contriving, the free end of which is bent obtusely so that injuries may be avoided.—*New York Polyclinic*, June 15, 1897.

#### *A BRIEF CONSIDERATION OF SOME UNUSUAL TYPES OF FRACTURES AND DISLOCATIONS OF BONES LIABLE TO BE OVERLOOKED.*

The following conclusions are reached by MANLEY (*Virginia Medical Semi-Monthly*, June 25, 1897) in a paper with the above title:

1. Fractures, difficult or impossible of demonstration—as those fissured vertically, or those non-displaced through the cancellous tissue of the articular ends of long bones—occur without doubt more frequently than is commonly supposed.

2. In injuries of the limbs attended with unusual or doubtful fracture, nothing can justify the application of violence to demonstrate its presence, as in no event are the principles of therapy altered in them.

3. In this class of cases the patient should be given the benefit of the doubt until, at least, time elucidates it—caution only being observed that the circulation is unhampered and full muscular relaxation is effected.

4. We should never fail to utilize the Roentgen rays as a diagnostic aid when possible, though their use in this direction is obviously limited.

5. Exploratory incision should be ruled out, unless the fracture is of such description as to demand or justify a simultaneous osteoplastic operation.

#### ON SOME SUPPURATIONS OF THE URINARY APPARATUS.

REGINALD HARRISON (*The Lancet*, June 26, 1897) in an admirable paper has selected for consideration some points which seem to arise out of the pathology of certain suppurative processes as observed in the urinary organs in relation to the more modern treatment of surgical lesions and infections as generally practised. He first illustrates his observations by taking the most common, as well as the farthest reaching, cause of suppurations of the urinary organs, occurring in the form of primary gonorrheal infections in the male and the female, and as secondary developments in other parts of the genito-urinary system, as more frequently observed in the latter sex. The advances that have been made in connection with the bacteriology of the urinary organs in reference to the kind and extent of these infections have already led to the most useful applications in the way of treatment. The investigations of Guyon, Janet, Halle, and others of the French school, more particularly as regards the life-history and cultivation of these micro-organisms, are of much interest and importance. The first point that strikes one is that many of the cases spoken of as instances of chronic suppurative urethritis or gleet represent a far more extensive invasion than is generally supposed to be the case.

In this lies an explanation of the difficulty that is not infrequently experienced in bringing cases of this kind to a successful and speedy termination. Many gleets are merely reinfections of the urethra from the bladder, which serves the purpose of a medium for bacterial cultivation. So long as a gonorrhea is confined to the area of the urethra, as defined by that portion of the canal which lies in front of the compressor urethræ, or "cut-off" muscle, the task of successfully combating the infecting suppuration is not usually a difficult one. The disease is within limits which can be readily acted upon by various agencies, administered either locally or by internal medication, and its course is generally limited both in severity and duration. When, however, these boundaries are exceeded and the bladder becomes invaded, it is not easy to prevent reinfection taking place as if from an extraneous source. Hence the disease may be almost indefinitely protracted. Nor is invasion of the bladder in this way uncommon or necessarily indicated by acute symptoms such as would unmistakably draw attention to the occurrence. In most instances of this the prostate is the only part of the urinary apparatus that may show any active indication of contact with septic products, the mucous membrane of the bladder, though harboring them, being singularly insensitive to bacterial influences. That infection occurs in this way may be readily demonstrated. When the bladder has been thus involved the conditions of the urinary organs, particularly during the night, are extremely favorable for bacterial cultivations, a circumstance which may explain the constancy and degree of matutinal suppuration exuded by the urethra, which is a prominent symptom in this class of cases. It is rare, the author believes, for gonorrheal organisms to make their way up the ureters and to invade the kidneys—a fact which is no doubt due to the guarded manner in which these ducts enter the bladder, and the constancy of the downward flow of the urine. That renal infection and urethral inflammation sufficient to cause a pyelitis of the former and a contraction or stricture of the latter can occur has been demonstrated as possible. Some years ago he examined the body of a middle-aged man who died from acute single pyelitis rapidly following upon a first attack of gonorrhea. The ureter of the kidney involved was extremely dilated, a circumstance which was believed to be due to the fact that the patient for some years pre-

viously had been passing renal calculi. The opposite kidney was much congested. Mr. W. G. Nash has recorded a case of strictured ureter which was probably caused in this way. In the female the wide-spread effects of the gonorrheal infection are generally recognized.

The suspicion, however, that the bladder may be infected with micro-organisms should be made a matter of proof, and this can generally be done. For this purpose care should be taken to obtain a specimen of the urine as it exists in the bladder, minus any contaminations it may pick up in its transit along the urethra. The first portion of the urine passed should be rejected as probably containing the flushings of the canal, the balance being separately collected as representing the constituents of what may be called vesical urine. When it is possible a catheter specimen should be obtained, where there are reasons for believing that the bladder is infected. In this way gonococci may be detected in vesical urine in cases of gonorrhea. The mere fact that the urine is shown to contain bacteria does not necessarily imply that the individual is capable of inoculating another with gonorrhea. Where, however, the gonococcus is discovered in the urine or the discharges of the patient, as is not infrequently the case, the author does not think there can be any doubt as to the possibility of its communication to some one else. The bacteriological examination of these secretions may furnish important evidence in determining whether a person who has been comparatively recently infected should be allowed to marry. So long as these conveyers of infection can be detected in the urine or the discharges, so long may we expect that transference of the disease is liable to follow. In these cases of secondary infection of the bladder, caused by extension from the urethra, he has for some time placed much reliance upon the irrigation of the bladder and urethra with antiseptics, as described by Dr. Janet, with some modifications. The object is attained in the following manner:

The apparatus consists of an ordinary hydrostatic bladder-tank, holding about one pint of water, and fitted with a nozzle, to which a No. 8 Jacques' rubber catheter can be attached. The tank is elevated about six feet from the ground, and is filled with warm water containing thirty minims of Condé's fluid to a pint of the water. For lubricating the catheter he uses carbolized vaselin. The patient having emptied his bladder spon-

taneously is placed in the recumbent position, and the catheter is then passed. Before the nozzle of the irrigator is connected with the catheter as it lies in the bladder the fluid is allowed to run off for a few seconds so as to ensure that there is no free air in the tube of the apparatus. Then the connection is made and the fluid is allowed to flow into the bladder by degrees until the patient is conscious of feeling distention. He generally uses from twelve to sixteen ounces for this purpose, allowing it to enter the bladder in jets of about three or four ounces at a time. In this way the feeling of any sudden or extreme fullness is avoided, and the entire area of the mucous membrane of the bladder is unfolded and opened out, and thus comes in contact with the permanganate solution. When a sufficient degree of bladder distention is obtained the catheter is slowly removed, care being taken not to allow the fluid to escape. He then usually lightly palpates the bladder above the pubes with the hand before the patient stands up. This he should then do and proceed to empty his bladder of its contents by his natural efforts. Thus not only is the bladder washed out, but the whole urethra is flushed in a manner that is impossible by any artificial means. As the patient is voiding the contents of his bladder, it is well to direct him to suddenly interrupt the outflow once or twice by pressure with the finger on the penile urethra. In this way the lacunæ of the canal are also distended and flushed by the irrigating fluid. This completes the process, which may be repeated once or twice in the twenty-four hours, until the urine and the urethral mucus are found free from organisms. Most patients after proper instruction will be able to carry out all these details. On the conclusion of each irrigation the patient should rest for a time in the recumbent position. The author has only referred to the permanganate of potash in great dilution as the flushing agent for use in these cases. Half a drachm of Condé's solution, gradually increased to a drachm, in a pint of water, has given him good results. Neutral sulphate of quinine (one grain to the ounce) may also be used. More rarely he has employed nitrate of silver (one-sixteenth grain to the ounce) and perchloride of mercury. The last sometimes produces a great deal of pain, though only used in the proportion of 1 in 10,000. He has no doubt for aborting infections the perchloride is the most effective. When used for the latter purpose in the proportion of 1 in 10,000, and after the solution has

been spontaneously voided from the bladder as in the act of micturition, the bladder may be filled with a strained solution of albumen—say that yielded by one fresh egg—in a pint of tepid or nearly cold water. If this is done and the albuminoid solution voided in like manner from the bladder, any pain, smarting, or spasm that the perchloride solution produced at once ceases. Similarly, a weak solution of chloride of sodium, injected into the bladder after a solution of nitrate of silver has been used for this purpose, not only removes any irritation the latter may provoke, but coats over the inflamed mucous membrane with a thin layer of chloride of silver, which often affords much relief when cystitis is present. Probably there is no better bactericide than nitrate of silver in these cases, but it requires to be used with the precautions mentioned, when good results may be obtained. In this class of cases, where suppuration proceeds directly from infection, the internal administration of bactericides may be advantageously combined with the local treatment just referred to. In rendering the urine sterile and destructive to the life of the gonococcus there are no more effectual agencies than some of those which are derived from the vegetable kingdom. He refers particularly to the volatile oils which are so largely eliminated by the kidneys, such as sandalwood, copaiba, cubebs, and similar drugs. By these it is possible to so saturate the urine as to render the existence of certain forms of bacteria impossible.

The author then notices other varieties of urinary suppurations, which may be best illustrated by certain cases of prostatic obstruction. Though the urine is in these instances usually purulent and charged with bacteria, the latter are not infective in the same sense as those he has previously referred to in connection with a special form of urinary suppuration. On the other hand, it must be remembered that these micro-organisms are readily capable of transference from one individual to another through the medium of catheters and instruments of this kind, and thus they may be regarded as factors in the causation of extensive and far-reaching suppuration in these parts. The principles of treatment in this class of suppurations are the same as those he has already mentioned, subject to certain modifications which he proceeds to notice. Putting aside the consideration of the precise means which these cases often require for mechanically emptying the bladder and thus preventing decom-

position of the urine taking place, the restoration of the secretion to its normal state will be mainly brought about by antiseptics in the manner indicated. The more or less atonic condition of the bladder in these obstructive cases seldom permits us to employ the process of autoirrigation as previously described, and we must therefore for this purpose avail ourselves of one or other of the methods usually practised.

As to the toilet of the bladder: (1) The disposition of the parts requiring ablution; (2) the mechanism employed; and (3) the composition of the cleansing fluid. Most of us will admit that we are disposed to draw our ideas relative to the process of washing out the bladder from the natural state of the parts such as we see in anatomical plates. If, however, we select for our guidance the majority of pathological specimens illustrating the obstructive diseases of these parts, we shall at once recognize the difficulties that beset us in our endeavor to wash out these, as we should do, for instance, in the case of a pint vessel. Take for example, the hypertrophied bladders, with their various saccules, pouches, and dependencies, which are met with in connection with advanced urethral stricture in younger adults and in persons of more advanced age who are the subjects of obstructive prostatic disease. In many of these the bladder is no more like the natural organ than the interior of a glass bowl resembles the section of a coarse bath sponge. The contents of the latter we could hardly ever hope to wash out effectually, though we may succeed in soaking them out. For washing out the bladder he almost invariably employs the hydrostatic tank; it has many advantages over syringes. When the bladder is much fasciculated it should be done in the recumbent position, with the object of opening out the mucous membrane as completely as possible without causing pain, so as to reach irregularities on the surface which otherwise would escape contact with the lotion. When the bladder is much pouched it is a good plan, after filling it and before removing the fluid, to cause the patient to agitate his body from side to side so as to bring any dependencies there may be within reach of the antiseptic. In various ways such as these the process of washing out the bladder may be rendered more searching. For washing out in ordinary cases of bacterial urine he usually prefers boracic acid or the boroglyceride. Condy's fluid and iodoform may also be similarly employed.

The sterilization of the urine by internal medicines is an important adjunct in the treatment of the class of cases which the author is now referring to. It is quite unnecessary to draw attention to the many obvious ways in which the urine may thus be altered. The specific gravity, the reaction, and the composition of this secretion may to a large extent be artificially influenced, and in these directions the course of suppurative diseases of the urine passages may be importantly and favorably acted upon. He has already referred to the sterilizing influence that certain oils and essences, such as sandalwood and copaiba, are capable of exercising in this way. No less marked is the effect that boracic acid taken internally is capable of effecting in controlling bacterial life in the urine. Probably no better proof of this exists than in the results observed in connection with operations on the urethra, such as the passing of catheters and in internal urethrotomy. The late Dr. Palmer, of Louisville, showed many years ago that by the use of boracic acid beforehand the development of urethral rigors and fever under these circumstances was rendered highly improbable, and this has since been amply proved to be the case. Similarly the use of quinine as a prophylactic against urine fever has been shown to be most efficacious; salol and other like drugs are also well recognized as urine sterilizers. Though boracic acid in doses of ten to fifteen grains three or four times in the day is probably one of the most reliable sterilizers, it so often disagrees and causes dyspepsia as to interfere greatly with its use for the purpose. Some years ago the author's attention was called to a preparation called boro-citrate of magnesia, which was described by Dr. Koehler, of Kosten, in Germany, as a solvent for uric acid calculi, and gravel. In the communication referred to it is stated that it is prepared by dissolving boracite, a natural borate of magnesia which is found in Stassfurt, in citric acid. Whether it is actually a solvent for uric acid he is not prepared to say. Whilst testing it for this purpose he found that it frequently had a remarkable effect in sterilizing and clearing up purulent urine and in favoring the expulsion of calculi and gravel by its flushing effects on the urine passages. For the latter purpose he has used it for the last ten years in conjunction with other means for preventing urine decomposition, with considerable effect. He is now in the habit of prescribing it in teaspoonful doses in half a tumbler or so of either warm

or cold water two or three times in the day. We have other means for sterilizing the urine by the mouth. No one method or drug is universally applicable. There is a combination of the salicylate of soda with the benzoate of soda which possesses this power in a marked degree. He has frequently found urine which has been rendered opaque by the presence of pus, and swarming with bacteria, rendered clear in the course of a few days after the use of this preparation. He usually prescribes fifteen grains of both of these salts to be taken together three times a day in an ounce of chloroform water. The hyposulphite of soda in half-drachm doses has also in some instances effected the same object.

The principle of urine sterilization may, however, be extended to other purulent or bacterial conditions of the urinary apparatus. He refers more particularly to some of these chronic suppurations resulting from the formation of abscesses in connection with the prostate and prostatic urethra, where the pus was originally discharged, sometimes against gravity, into the latter canal. These are often most difficult to heal, by reason of the absence of a free and depending opening. Yet, on the other hand, the opening of the perineum and the incising of the prostate to secure free drainage of the discharge is a proceeding that cannot always be undertaken without some degree of risk in elderly subjects. The thorough cleansing of these deep parts by the use of antiseptics in the form of autoirrigation will be found efficacious in many of these cases of chronic suppuration. In some instances of prostatic suppuration it is almost impossible to flush a sinus connected with this part so long as a catheter of any kind is retained in the bladder. On the other hand, this object may be readily effected by the spontaneous contraction of a bladder more or less distended with fluid. In the sinuses, for instance, arising out of tuberculous prostatitis, this method usually proves very effectual. Again, he has resorted to this way of flushing urinary fistulæ with some antiseptic fluid when the primary cause of them has been removed, as by gradual dilatation or after internal urethrotomy. Tortuous routes through the perineum may, by washing out through the medium of the bladder two or three times if necessary in the twenty-four hours, be thus healed.

A few months ago Harrison saw a middle-aged man with a tight stricture in the deep urethra, which only admitted a No. 4 bougie.

In addition there were two chronic perineal fistulæ—one opening in the left buttock and the other by the side of the scrotum—through which almost the whole of the urine was passed at the time of micturition. The patient's condition was an extremely distressing one, as it was impossible for him to pass urine with any degree of comfort except upon a water-closet. The author divided the stricture from within by Maisonneuve's urethrotome. A catheter was then tied in the bladder for forty-eight hours, and on its removal a No. 12 silk catheter *à boucle* was introduced morning and evening. After washing out by means of this in the ordinary way the bladder was finally filled with about a pint of warm boracic lotion, which the patient was required to void naturally in the standing position on the catheter being withdrawn. The fluid escaped as in the ordinary act of micturition with this patient—namely, partly by the urethra and partly through the false routes. The proportion of the fluid coming through the urethra gradually increased, whilst that passing through the two fistulæ grew less daily, and in the course of ten days entirely ceased. This method of procedure he has found from repeated trials to contribute importantly in promoting the sound healing of these sinuses and the comfort and cleanliness of the patient.

#### IMMEDIATE SUTURE OF THE BLADDER AFTER SUPRAPUBIC CYSTOTOMY.

DE FALACCOS advocates immediate suture of the bladder after suprapubic cystotomy, and thinks it should be employed in almost every case, irrespective of the condition for which the operation was performed or the age of the patient, and refers to numerous successful cases. He prefers catgut for suture material and uses a catheter *à demeure*. He allows his patients to get up at the end of a fortnight as a rule.—*Boston Medical and Surgical Journal*, June 24, 1897.

---

#### ACTINOMYCOTIC TYPHLITIS AND APPENDICITIS.

GANGOLPHE and DUPLANT (*Revue de Chirurgie*, June 10, 1897) excellently summarize the knowledge of this subject. As to the symptomatology, the first manifestations of the disease are variable; sometimes a pericæcal or parietal tumor is the symptom common to appendicitis. The germ undoubtedly penetrates with a foreign body.

The stagnation of the intestinal contents in the cæcum favors the localization of the parasite at this point. The intubation is probably long. Müller has reported a case in which the hand was affected showing that the disease had an incubation of two years. Prodromes of the affection are extremely vague—dull pain, localized tenderness, gastro intestinal disorders. The intestinal symptoms are characterized by pain in the right iliac fossa, either acute or dull, sudden or gradual in onset. There is usually marked diarrhea, with the passage of mucus or even dysenteric feces. This diarrhea is persistent, sometimes alternating with periods of constipation. There may be vomiting associated with it. At this period there are usually no physical signs—even tenderness may be absent. After a variable time there is the development of a tumor; the parasite having passed beyond the intestine invades the surrounding tissues without any regard for their anatomical relations. The infiltration is rapid and at first extremely hard; the mass is fixed, and on section the tissues creak. Involvement of the skin is always slow, and even though adherent it may not seem to be inflamed. Usually palpation does not cause pain. Infiltration extends rather toward the surface than toward the deeper parts. Inevitably there follows a softening, usually preceded by pain. The skin becomes violaceous in color. Softening takes place rapidly. The liquid discharged is at first clear, then becomes gray, and contains yellow grains. The walls of the abscess are thick and granular. Fistulæ always form, usually direct, with punctiform external orifices surrounded by a button of granulations. The pus from these fistulous tracts contains the yellow grains. The tumor may be softened in several parts at the same time or consecutively. In the fatal cases the patient rapidly becomes cachectic and there is obstinate constipation. The temperature is rarely high. There is neither lymphatic tumefaction nor ascites.

Regression of the lesions is rare. The progress of the affection is essentially slow. The duration ranges from one to four years, eighty per cent. of cases terminating fatally either by peritoneal or hepatic complications or progressive cachexia. Metastasis to the liver is common and is nearly always fatal. Actinomycosis may reach the posterior portion of the abdomen through the mesentery; this method of evolution is nearly always fatal.

There is a strong predisposition toward mixed infection. One case reported by the authors was attacked by erysipelas; the yellow grains entirely disappeared upon the subsidence of this disease, and the infiltration disappeared entirely. The disease is most common between the thirty-fifth and forty-fifth years, and in men. Infection seems to be frequently carried by cereals.

Diagnosis is extremely difficult in the early stages; indeed, it is impossible to differentiate this affection from ordinary appendicitis. Slow onset, moderate pain, marked and obstinate diarrhea, and slight constitutional symptoms may possibly suggest the nature of the disease. When a tumor is formed, absence of pain, intense induration, normal color of the skin, absence of local hyperthermia are suggestive.

Tubercular peritonitis is readily excluded, since it exhibits disseminated lesions, is associated with ascites, and does not infiltrate the external teguments. Fibromata of the abdominal walls are not accompanied by intestinal phenomena, are oval, oblique, from above downward and without inward, and nearly always painless. They are fixed by muscular contraction and mobile when the muscles are relaxed; usually found in women during the genital period; and the overlying skin is healthy. Sarcomata of the iliac bones ulcerate very slowly from a circumscribed tumor strongly adherent to the bone, and until they attain large size are not accompanied by intestinal phenomena.

When fistulization has taken place the presence of yellow grains in the discharge, the multiplicity of the tracts, their peculiar openings, and the conformation of the cavities into which these tracts open, make a positive diagnosis possible. Tuberculous typhlitis might be extremely difficult to distinguish from the actinomycotic infection. In the former invasion of the abdominal wall by the ulcer is extremely rare.

Gangolphe has reported eleven cases of inflammations of the abdominal walls due to malignant tumors of the large intestine. In addition to the peculiar character of these inflammations due to secondary microbic infection, it should be recalled that intestinal disorders and occlusion or constipation precede the appearance of the inflammatory phenomena, which are localized in the supraumbilical region.

During the period when diagnosis cannot be confirmed medical treatment is indicated. If actinomycosis is suspected, iodide of potas-

sium should be given in doses of from eight to thirty grains. It may be happily associated with arsenic; moreover, the treatment common to mild cases of appendicitis is appropriate. When tumor is formed internal medication is still indicated, and the iodide may be advantageously associated with calomel. Operation should, however, be performed at once, and as far as possible all the infiltrated tissues should be removed. If extirpation is impossible free incision should be made into the indurated tissues. The fistulous tracts should be made to intercommunicate and should be washed out with a one-per-cent. solution of potassium iodide, ten quarts being employed at each dressing. A compress is then applied impregnated with this solution. Neither curetting nor excision of the fistulous tracts is of any service.

#### THE TREATMENT OF REBELLIOUS CYSTITIS IN WOMEN.

ESCAT (*Ann. des Mal. des Org. Génito-Urin.*, February, 1897, p. 132) states that when cystitis proves rebellious to instillations, injections, or washings, curettage through the urethra is indicated. This is extremely serviceable in suitable cases, but should not be employed when there is kidney disease or when the inflammation has penetrated deeply into the bladder-walls. If the inflammation has extended beyond the trigonum, suprapubic cystotomy followed by curettage is indicated. Seven cases of chronic cystitis were reported in which not only was the curette employed but portions which resisted this instrument were touched with the actual cautery. In three other patients suprapubic cystotomy was unavailing. Vaginal cystotomy was, however, followed by cure. In cases thus treated the vesico-vaginal fistula should be kept open for a long time. The following conclusions were appended to this paper:

When a cystitis is observed in which ordinary treatment is unavailing, a very careful examination should be made for disease of the pelvic organs. The urethra should also be subjected to thorough exploration, and the urine should be repeatedly analyzed to detect the presence of kidney disease. When the ordinary means of treatment have failed and it is quite certain that the kidneys are healthy, suprapubic section is indicated, followed by destruction of all of the diseased mucous membrane, and temporary drainage. When the kidneys are diseased or the general con-

dition of the patient is bad, vaginal cystotomy is indicated, with drainage continued for a long time.

#### RUPTURE OF THE BLADDER.

HÖGERSTEDT (*St. Petersburger Medicinische Wochenschrift*, 1896, No. 30; *Centralblatt für die Krankheiten der Harn- und Sex.-Org.*, bd. viii, h. 6, 1897) writes of those rare cases in which the symptoms of the wound of the bladder do not develop for several days after the injury. In his case the patient three days after a fall suddenly experienced, in endeavoring to urinate, agonizing cutting pain in the region of the bladder, and was unable to micturate. The catheter drew a pint of urine containing many red blood-corpuscles. After this the patient was absolutely unable to pass his urine spontaneously, and seven days from the development of the first bladder symptom the patient died of peritonitis. It is apparent that the rupture did not originally involve the peritoneal coat, but as a result of inflammation this structure was so weakened that it was unable to resist the increased pressure incident to the effort at urination. This case and others like it show the importance of examining the urine for blood immediately following traumatism, and if this be found in any considerable quantity, and it is evident from the history of the case that the bladder is probably wounded, the application of continuous catheterization for several days.

STUBENRATH (*Archiv für Klinische Chirurgie*, bd. li, heft 2) has conducted experimental investigations on the elasticity and strength of the bladder and upon the mechanism of rupture, founding this latter study upon a statistical collection of cases in which either operation or autopsy demonstrated the seat or the nature of the lesion. His conclusions are as follows: Isolated traumatic rupture of the bladder can occur only when considerable violence is exerted directly upon this organ, when the organ is at least partly filled with urine. Rupture of the bladder usually occurs as a result of overdistention of the organ. Only exceptionally is it noted in the fixed portions as the result of direct violence. The violence always occurs in the weakest portions, but it is noteworthy that the weakest part from an anatomical standpoint is not necessarily so mechanically. The posterior upper portion of the viscus is usually the seat of tear in seventy out of 154 cases. The cause of rupture in this part of the organ can

be attributed neither to pressure from the promontory nor to the longitudinal direction of the muscular fibers of the posterior wall. Comparatively large spaces between the muscular fibers in this region, and lack of support, seem to be the main causes of rupture in this locality. Ruptures may be multiple. The direction of tear is dependent upon the course of the muscular fibers, not upon the form of violence. The rupture may be complete or incomplete. Experimentally incomplete ruptures are commonly due to force working slowly. These incomplete ruptures prove that the tear is from within outward. At first the mucous membrane gives way, then the muscular coat, and finally the peritoneum.

#### INTRAPERITONEAL RUPTURE OF THE BLADDER.

WALTER (*Vratch*, 1896, No. 46; *Centralblatt für die Krankheiten der Harn- und Sexual-Organen*, bd. viii, h. 6, 1897) states that in the Obuchow Hospital nine cases of intraperitoneal traumatic rupture of the bladder were treated. Eight of these were operated on, seven died in from two to seven days of peritonitis, and two recovered. One case, aged forty-four, was operated on fourteen hours after the fall. A tear two inches long was found in the posterior wall of the bladder. It was closed by the Lembert-Czerny suture. Perineal urethrotomy was then performed, and the bladder was drained for fourteen days. This patient recovered.

The second successful case was a man forty-eight years old, who was operated on thirty hours after injury. The lesions were found in the posterior wall; there was a tear two and a half inches long through all the coats, five inches long through the serosa. The borders of this tear were freshened, and the wound was closed by two layers of suture. Continuous catheterization was employed for three days. The abdominal wound was not completely closed, tampons being placed in the pelvis. After five days this tampon was found soaked with urine. A fistula formed, which, however, thoroughly closed.

#### ACTION OF CHLOROFORM OR ETHER UPON THE KIDNEY.

LEGRAIN (*Ann. des Mal. des Org. Génito-Urin.*, No. 2, p. 191, 1897) examined the urine of fifty-four people after chloroform anesthesia, and of forty-one cases after ether anesthetization. Narcosis in the chloroform

cases lasted on an average fifty-seven minutes, and in the ether cases one and a half hours. There were ten cases of albuminuria and cylindruria after chloroform; fifteen cases after ether. In three of this last series there was preexisting kidney disease. Autopsy was made in two of the ether cases, and profuse hemorrhagic nephritis affecting especially the glomeruli was found. Experimental investigation upon animals gave similar results. Especially characteristic of ether were the strong congestion and multiple hemorrhages in the parenchyma of the kidneys. After chloroform the animals experimented upon did not show glomeruli nephritis with fatty degeneration, or necrosis of the epithelium of the tubules and the extravasations of leucocytes about the glomeruli and into the parenchyma.

The author concludes that albumen is more frequently observed in the urine after ether than after chloroform, but that the nephritis caused by ether is transitory, whilst that due to chloroform is likely to become chronic.

**LIGATURE OF CAROTID ARTERIES FOR THE CONTROL OF HEMORRHAGE DUE TO PHARYNGEAL ABSCESS.**

At a recent meeting of the Royal Medical and Chirurgical Society CLUTTON (*British Medical Journal*, May 29, 1897, p. 1349) reported the case of a victualer, twenty-eight years old, with a history of having bled rather profusely the day before from an abscess in the pharynx above the right tonsil. After the lapse of a few days the soft palate was divided for the purpose of a complete examination of the abscess. A hole was found passing through the wall of the pharynx into the tissues of the neck. This opening was enlarged and the cavity plugged with cyanide gauze, as it was thought from the character of the hemorrhage that the bleeding might be from the internal jugular vein. During the night following this operation the man bled so furiously that no doubt could be entertained as to the hemorrhage being from a large artery, probably the internal carotid. On the following day the bifurcation of the common carotid on the right side was exposed and an animal ligature applied by means of a stay-knot to the common carotid and its two branches. A saline infusion of two pints was given whilst the wound was being closed with sutures. The wound in the neck healed by first intention, and the abscess cavity in the pharynx was found by digital examination some time

later to have closed. There was no further hemorrhage after ligature of the carotid arteries.—*Journal of the American Medical Association*, July 10, 1897.

---

**SUCCESSFUL REMOVAL OF BRAIN TUMOR, WITH PERMANENT RECOVERY.**

ZIEHL and ROTH (*Deutsche Medicinische Wochenschrift*, May 6, 1897, p. 297) have reported the case of a man, sixty years old, who, in the midst of perfect health, was suddenly seized with a peculiar rigidity of the thumb and index finger of the right hand, followed by loss of consciousness for several minutes, but without twitching or convulsion. With the return of consciousness vomiting took place. The gait was somewhat staggering, but there was no paralysis. On the following day the patient had returned to his usual health. Rather more than six weeks later the man was seized with transient tonic followed by clonic spasm of the right hand, without loss of consciousness. After another interval of about the same duration he was awakened at night by severe headache and found himself paralyzed on the right side. In the course of two weeks the palsy of the lower extremities had receded to such a degree that the man could walk, while that of the upper extremities subsided rather more slowly. From time to time, however, the right upper extremity was the seat of clonic spasm, always beginning in the thumb and index finger. At times the entire right side of the body was involved. These attacks were followed by headache, which was absent in the intervals. A small area of tenderness was detected in the right parietal region, which subsequently became edematous. No ophthalmoscopic changes were found. It was learned that the patient had had a chancre at the age of twenty-three years, but secondary symptoms had not been observed. Two or three years before coming under observation he had fallen and struck his head. The use of potassium iodide was unattended with relief, while mercurial inunctions were followed by amelioration of the headache following the attacks of loss of consciousness, although without effect upon the attacks themselves. Memory beginning to fail and the general condition to suffer, trephining was decided upon. Accordingly the motor area for the right thumb and index finger was exposed. The bone was found hard and dense and covered on its surface by

hyperostoses and osteophytes. The dura was covered with a brownish-red mass resembling granulation tissue, a portion of which was adherent to the overlying and eroded bone. The adventitious material was removed, together with the involved bone, and the wound was tamponed and closed. Histologically the material was found to be constituted of round cells. The surgical progress of the case was uncomplicated, but the convulsive attacks recurred, and finally the condition of the patient became so aggravated that a second operation was undertaken at the site of the first, the dura being now opened and a collection of material similar to that found originally removed. This, on microscopic examination, proved to be an angiosarcoma. The operation was followed by right hemiplegia and paraphasia, and impaired sensibility in the right arm. Later, however, progressive improvement set in, with almost complete restoration of function, and this condition was still present more than two years after the second operation.—*Journal of the American Medical Association*, July 10, 1897.

AN EASY AND RAPID METHOD OF FIX-  
ING THE URETERS IN THE INTES-  
TINES WITHOUT SUTURES BY  
THE AID OF A SPECIAL BUT-  
TON; WITH EXPERIMEN-  
TAL RESEARCHES.

In a paper contributed by ACHILLE BOARI to the *Columbus Medical Journal* of July 6, 1897, the writer describes a button which consists of a collar-button with quadrilateral base, which he has devised for the above purpose, and details a number of experiments which gave the following results:

1. The button was expelled the tenth or twelfth day. Fearing, therefore, that the cicatrization would not be complete in so short a time, the author has modified the head of the button, making it less cutting and rounder, in order that the ureter may be longer in effecting its separation.

2. The extraperitoneal route recommended by Chaput and which they followed is very convenient for the grafting of the left ureter upon the descending colon. The operative lesion is not very severe, but the technique of the grafting with the forceps seems clumsy. For this reason the author has tried to simplify it.

3. The first discharge from the rectum occurred in one case in fifteen hours, in the other twenty-four hours, after the operation, and was of small quantity (25-30 cubic centi-

meters); while the others succeeded them with an interval of two to four hours, and a mean quantity of 100 cubic centimeters. This causes him to think that the bilateral graft at a single operation is dangerous, because in these cases during the first fifteen to twenty-four hours the organism will probably be exposed to dangers from uremia, either from suppression of urinary secretion or prolonged stagnation thereof.

The graft is made upon the rectum or the colon by proceeding in the sacral way. Although the experiment guarantees the success of the operation, nevertheless, when the operation is upon the human subject it is better to make the graft outside the peritoneum, because should it happen to fail then the patient will not perish from peritonitis. At the worst, a urinary fistula will remain, which can be repaired later. By whatever way we proceed, we choose a button adapted to the caliber of the ureter, which is dilatable, invaginate the end of the ureter upon the tube and then fasten it with fine silk, lower the small movable plate until it joins perfectly the inferior one, and then according to the last modification the central portion of the tube has a transverse opening; pass into this opening a steel stylet of proper caliber, which is used to control the button and at the same time compress the cock, thus replacing the forceps. With a needle well mounted with fine silk circumscribe the point of the intestine into which the graft should enter with an oval line of purse-string suture. In this part thus circumscribed, which ought to be neither too large nor too small, make a long longitudinal incision sufficient to allow a large part of the button to pass with a little resistance. This done, locate the button in the intestinal incision with the aid of the stylet transversely to the line of the incision. The operator ties the end of the silk in a surgical knot and tightens it. The whole line of the suture is narrowed into folds and is applied to the central tube of the button.

In this situation the operator, making traction upon the thread, directs the assistant to withdraw the stylet, then the lock is depressed and the button closed. It only remains to make a second knot and the graft is made complete.

Boari compares this maneuver to that commonly made in definitive hemostasis, where one closes an artery by a knot with the aid of forceps. It no longer bleeds, and the operator adds a second knot to hold the first and compress the tissues still more; while by the

first method, which he described in the *Polí-clínico*, vol. 11, C., fasc. 10, 1897, in using the forceps it was necessary to make a suture at separate points, and the use of the forceps was inconvenient. By the last procedure, on the contrary, the operation is done with the greatest facility and rapidity, since it is done in a few minutes. Besides, the intestinal button-hole is with the aid of the stylet applied closely at all points to the metallic tube, so that the retraction of this portion, be it ever so small, from the intestine is impossible, and there is no reason to fear that it will yield.

After having made the graft upon a cadaver, the author tied the end of the intestine and filled it with water, and the water did not escape except by the ureter; even when the latter was compressed by one knot the suture did not allow the water to escape.

The groove which after the first modification he placed in the superior movable plate has great importance: (1) It responds, as experiments have shown him very well, to better closure next to the internal border of the intestinal button-hole; (2) it gives the ureter a larger surface for lateral adhesion, since it surrounds the intestine above the point where it should necrose.

The pressure of the threads upon the borders, which they cause to mortify, causes the button to fall, and when the button escapes through the anus it ought to bear, attached to the stock, the lace of silk which sewed the ureter as well as that which sewed the intestine. This demonstrates that the grafting has fully succeeded. If after the operation has been completed there remains a doubt, we may back up a little zone of intestine upon the ureter by the aid of sero-serous sutures.

In the author's last experiments he has tried to preserve the tissues up to the sphincter either by infixing with the aid of the button (large) the trigone and the openings of both ureters, or by fixing the ureter of one side and leaving around it a little collar of vesico-mucous membrane, which can be fastened above one of his buttons, and fixing it by the aid of a circular lace; but this cannot be done always.

In the large ulcerations of the ureter, in malignant tumors occupying the trigone it is necessary to make the infixation of that portion of the ureter which is sound. This is why he has recourse to artifices which may act as a valve. He has fixed the ureters upon the lower portion of the small intestine eight or ten centimeters above the cæcal valve, and he has sewed the superior portion

of the small intestine by a lateral anastomosis upon the large intestine at a point beyond the valve in such a way that it could be called to defend the kidneys in hindering the regurgitation of the intestinal contents toward the ureter.

If, notwithstanding this artifice, experience should show an excessive frequency of renal infection, with the view of rendering the operation more worthy of being advised, there yet remains to us one precious recourse—the proposition of Giordano to make fixation of the ureters in the rectum and abolish the natural function of the rectum by an iliac anus. This is a half-measure which leaves a deformity, which is, however, more tolerable and less dangerous than that which comes from a double uretero-cutaneous fistula, and which at the outset has the advantage of prolonging the life of unfortunates who are affected with cancer of the bladder. We may yet dream of the creation of an artificial bladder by grafting the ureter upon a portion of resected intestine still nourished by its portion of mesentery; in reestablishing the continuity of the tube by means of anastomosis of both ends, and causing the loop thus isolated to discharge into the urethra as Poggi and Tizonni have proposed, or rather discharge its contents into some point of the colon as Chaput has said. Although those proceedings have not given complete results even to their inventors, nevertheless they contain in themselves, especially the first, the elements of so grand a conception that there is reason to think, if one should modify the experiments, the latter would end in happy results. However, there is always a necessity of having present in the mind beforehand these methods of difficult and grave intervention. It is necessary in the beginning to establish definitely the results of the bilateral graft of the ureters upon the intestines. There would be no recourse to the creation of an intestinal bladder except in case it should be demonstrated that grafting into the rectum, or into the colon, caused with it an infection of the kidneys, or else gave rise to too frequent discharges, which have not been demonstrated.

Even if it should result from experience that the orifices of the ureters with the lapse of time should become stenotic, we shall not yet confess ourselves to be vanquished. The author has thought of a lateral anastomosis of the ureters to the intestine, which would have the advantage of a larger opening to prevent the strictures.

## ANESTHESIA STATISTICS.

According to the Berlin correspondent of the *Medical Press and Circular* of June 30, 1897, GURLT presented the following statistics at the recent Surgical Congress at Göttingen:

For the years 1895-6, 1896-7: For the first year there were forty-four reports, comprising 29,596 cases; for the second forty-six reports, comprising 29,173 cases. The report therefore comprised 58,769 cases. There were 27,025 cases of chloroform anesthesia, with 29 deaths; 19,875 cases of ether narcosis, with 3 deaths; 4,927 cases with Billroth's mixture (chloroform, alcohol, and ether), 996 with bromide of ethyl, 5,890 with chloroform ether—with one death for the whole. The inquiry had been carried out since 1891, and the grand results for the period were 397,593 cases, with 134 deaths—one in 2444. From chloroform the deaths were one in 2,039 cases; from Billroth's mixture, one in 3,870; from ether, one in 5,000; from bromide of ethyl, one in 5,228; from chloroform-ether, one in 7,594; from pental, one in 213. The last named anesthetic did not appear at all in last year's report. The mortality varied a good deal in the different years. Thus from chloroform the mortality for 1897 was one in 1,126; in 1893, one in 4,200. In the first three reports there were no deaths from ether; in the later ones the mortality varied from one in 2,200 to one in 6,700. In the case of chloroform the relative number of deaths had increased during the last five years. As regarded chloroform, the fatalities were generally due to cardiac-paralysis; as regarded ether, pneumonia was generally the fatal factor. More lately kidney affections were observed after chloroform anesthesia, and exanthemata after ether narcosis.

## GONORRHEAL CYSTITIS IN WOMEN.

LINDHOLM (*Centralblatt für Gynäkologie*, No. 21, 1897) closely observed a girl of nineteen under treatment for gonorrhea which had distinctly involved the uterine mucous membrane. She began to complain of pain during micturition. On examining the urine gonococci were detected in pure culture. Through the cystoscope the vesical mucosa appeared very vascular, with superficial loss of substance at certain points. The cystitis was cured by washing out the bladder with warm boracic lotion and injection of a one-per-cent. solution of nitrate of silver.—*British Medical Journal*, July 3, 1897.

## REMOTE EFFECTS OF BONE TRAUMA.

Under this title D. S. FAIRCHILD (*Journal of the American Medical Association*, July 10, 1897) contributes an interesting addition to our knowledge:

The practical propositions involved in this paper are based on inflammation or irritation in bone following injury and the sequelæ resulting therefrom.

1. Resolution, including a complete restoration of the bone to its normal condition, occurs in the vast majority of cases.

2. Resulting in rarefying osteitis, condensing osteitis, or a combined rarefying and condensing osteitis, which may remain as a more or less permanent condition; if slight in degree giving rise to no well marked subjective or objective signs after the process becomes arrested.

3. If the process continues for a period beyond a few months, well marked and unmistakable changes in the physical condition and appearance of the bone will become manifest.

4. A persistent acute or chronic osteomyelitis will also give rise to unmistakable physical changes in the bone.

5. A persistent chronic osteoperiostitis will give rise to thickening of both periosteum and bone of a character that will readily be recognized if the bone is so situated as to admit of easy surface examination.

6. If the products of inflammation in cases of rarefying osteitis or in osteomyelitis become infected with pus-forming microbes, the suppurative process will become plainly evident, except in cases in which the process is very limited, giving rise to a small abscess in the bone which may be indicated only by subjective symptoms.

7. The injury and irritation following may establish a *locus minoris resistentiæ* which may become the seat of tubercular infection with certain definite results. The length of time after a trauma during which this influence may exist cannot be definitely determined, but it may be assumed in the light of critical practical experience and pathological research that the special predisposition will cease to exist as soon as the effused blood is absorbed, and the protoplasmic elements—the products of irritation and inflammation—have been resolved into new bone or have undergone degeneration and absorption—*i.e.*, as soon as the normal nutrition balance is restored. The author does not believe there is any scientific evidence or any practical facts that will bear criticism which will support the assumption

that the *locus minoris resistentiæ* may continue for months or years after all signs of the injury and its immediate results have disappeared.

8. There is no evidence to show that a carcinoma or sarcoma may develop as the result of an injury after the immature bone elements have been transformed into tissue of a normal resisting physiologic type.

#### THE ROENTGEN RAYS IN OSTEOPLASTIC SURGERY.

OLLIER (*Bulletin de l'Académie de Médecine*, No. 20, 1897) points out that, thanks to the delineations obtained from the Roentgen rays, it is no longer compulsory to wait until the patient's death before the actual dimensions and the exact form of newly developed bone can be made out. The surgeon is now able to make an autopsy of such formations on the living subject, and to examine them beneath the soft parts almost as distinctly as if they were directly exposed. Two cases are recorded in which the extent and form of new bone deposited after free removal of necrosed tibia were clearly shown by large skiagraphs. In one of these cases a portion of tibia about eleven inches in length had been removed from the leg of a girl eight and a half years of age; and in the second the patient, who was eleven years of age, had lost about nine inches of the lower half of the same bone. The drawings, taken some time after complete recovery, show in each case the outlines of the regenerated bone, which is less regular in form than that of the sound limb, somewhat uneven on its surface, but distinctly thicker than the opposite tibia. A third case is reported in which the picture produced by the rays showed a very satisfactory development of new bone produced by a long series of transplantations of periosteal and osseous grafts, practised with the object of filling up a large gap (about  $10\frac{1}{2}$  inches) formed after the removal of a large sequestrum in the tibia. The first attempt failed in consequence of necrosis of the graft, which was a portion about six inches in length, of the tibia of the sound leg, and the gap was not completely filled up until after repeated transplantation of fragments of bone from sheep and rabbits, and resection of a portion of the shaft of the fibula. Notwithstanding the failure of the effort to transplant a large fragment from the sound to the defective tibia, Ollier strongly advocates in such cases the practise of direct osteoplasty.

The transplanted fragment, however, must retain its periosteum, for if this membrane be wanting the operation will certainly prove sterile. The healthy tibia, it is stated, is a favorable source for preparing osteoplastic grafts, as this bone speedily repairs any loss of substance. The picture taken by the Roentgen rays in this case shows that the gap formed by the removal of the long piece of bone has been almost completely filled up. Fragments of healthy bone taken from a limb amputated for the results of recent injury form, it is asserted, excellent grafts.—*British Medical Journal*, July 3, 1897.

#### THE UMBILICAL CORD.

A. C. WENTZ (*Pennsylvania Medical Journal*, June, 1897), in an instructive and practical paper on this topic, says the methods of treatment of the cord are almost as numerous as the accoucheurs of the present day. They, however, are divided into the wet or greasy, and the dry or powder dressings. The wet dressings are lard, sweet oil, fresh unsalted butter, petrolatum, etc., in warm climates. The dry dressings are starch, iodoform, boric acid, salicylic acid, powdered acetanilid, bismuth, chalk, talcum, lycopodium, calomel, and others, used separately or one or several combined.

DOKTOR reports his experience relative to the treatment of the umbilicus in new-born infants, and the prevention of infection. In new-born infants the navel forms a columnar projection of the skin, on the top of which the cord is attached, a sharp line of demarcation, the navel-ring, separating the cord from the skin. On its margin are numerous vessels that go to the border of Wharton's gelatin, but do not enter it. When the cord is ligated its tissues lose their viability and must separate and fall away, leaving the wound covered with a living structure. This small wound is especially liable to infection and resultant maladies, light or severe: (1) Because of its condition; it is not merely a wound of the abdominal skin, but also of its walls, and in closest proximity to the peritoneum, which is very susceptible to infection. (2) The peculiarity that three great vessels lie free in this wound. (3) The disproportionately large mass of dead tissue, the remains of the cord. (4) The peculiar tendency to an excessive formation of granulations. (5) The frequency of development of anomalies and aberrations of the umbilicus also predisposes it to disease. Doktor suggests the prevention of

infection by cutting the cord as closely as possible and applying a careful antiseptic dressing, which should not be changed except for good cause. In preference to changing the dressing the bath should be omitted.

The following named physicians have kindly advised the author by letter of the treatment in the various institutions with which they are connected:

Dr. George M. Boyd, of Philadelphia Lying-in Charity: "Cord first stripped and pressure made from umbilicus toward placenta. Placenta knot made about three inches from umbilicus with bobbin; second knot placed one and a half inches from umbilicus; cord severed between knots. Should the cord be a thick one the second knot is not made. Stump held in fingers and before knot is placed the Jelly-Wharton exposed. In some cases to facilitate mummification a third knot is placed half an inch from umbilicus. The stump then has the two knots. The stump is then dusted with salicylic acid one part, starch five parts, wrapped in gauze, and binder applied. With this treatment we do not have suppuration, and the mass comes away usually in five days."

Dr. Charles P. Noble, of Kensington Hospital for Women: "The principles upon which the umbilical cord should be managed are: That it should be protected from infection on the part of the nurse by having her hands sterile when she handles it in the first cleansing or bath, and also subsequently; that it be dried after the first bath or cleansing, and then dressed in a dry, aseptic dressing. Sterile gauze is a very convenient dressing to wrap up the stump of the cord, over which is placed the belly-band. As a powder, bismuth subnitrate, with ten-per-cent. salicylic acid, or simple boric acid, is all that is used. In exceptional cases in which infection takes place and there is a discharge, the discharge is washed away with a peroxide of hydrogen solution, and the powder of salicylic acid and bismuth is applied. The cord usually comes away about the fifth day."

Dr. Barton Cooke Hirst, of the Maternity Department of the University of Pennsylvania, says he cuts the cord, holding it between the second and third fingers of his left hand and cutting with the point of the scissors turned toward the palm of that hand so that he cannot possibly do the child any injury. Before putting on the ligature he strips the cord of superfluous mucous tissue, pinching the vessels meanwhile to prevent hemor-

rhage. The nurse then holds the cord while he ties it firmly with an aseptic silk ligature. In dressing it he uses a pledget of salicylated cotton, put on the abdomen above the cord, on which he lays the stump, and over that another pledget of cotton which covers it entirely. This is held in place by the abdominal binder, and the cotton is changed every day when the child is washed, although any of it which clings to the cord firmly is not disturbed.

Dr. Howard A. Kelly writes the author the following as the treatment in use in the obstetrical wards of the Johns Hopkins Hospital: "Ligation one inch from umbilicus as soon as pulsation in the cord can no longer be felt, about eight inches from the child. For this purpose a double sterile ligature of heavy braided silk is used; the cord is then cut with a pair of sterile scissors between the ligatures. The child is given a full bath immediately after birth, and the cord is then dressed by wrapping it in a piece of sterile linen on which has been spread a little boric acid powder. The dressing is held in place by an ordinary abdominal binder. We make a point of keeping the cord perfectly dry until it drops off, and a dressing similar to the above is applied every morning. For this reason the child does not get another full bath until about the eighth or ninth day, but is simply thoroughly washed every morning by the nurse. They find the cord will drop off under the above treatment on about the eighth day."

With all these elegant aseptic treatments before us, what must be the lot of a poor country doctor, without sterile scissors, ligatures, linen gauze and cotton, hands, and nurse—sometimes only an "old granny" with her catnip tea to assist him. Yet these children do not all die—another evidence that Nature and pure country air are very helpful antagonists against septic poisons. The author's own experience for the last four years in the treatment of several hundred cases, with calomel in warm weather, and calomel 1 part and boric acid 7 parts by weight in cold weather, has been very successful. The method is as follows: After the ligation of the cord about one and a half and two and a half inches from the navel with boiled homespun linen thread, the cord is cut between the ligatures by scissors taken from strongly carbolyzed water. After the child is thoroughly washed and dried, the stump—especially the protruding vein and arteries at the end—the surrounding skin, even into the

groins, are well dusted with pure calomel. A clean old linen or muslin cloth about six by four inches, with a hole cut in the center, is thoroughly filled with calomel and placed on the abdomen. The stump is drawn through this hole. It is then laid toward the chest. The first fold of the cloth is made about one inch below the cord, also turned toward the chest; the second fold is made over this about one-third from right to left; the third fold is made about one-third from left to right. This entirely encases the stump in the calomel-cloth. The dressing is then held in place by the navel-band and safety-pins, pinned in front, for easy examination. The dressing is changed every morning after the child is washed and dried—great care being taken not to wet the stump at any time. By this method the cord, by desiccation, does not drop off until nine to sixteen days have elapsed. The umbilicus is thus thoroughly healed and usually shows no sign of red induration or pus in the fossa. After each bath the calomel, or calomel and boric acid, are applied for one or two weeks longer.

After long, unsatisfactory attempts in various methods, the author finally concluded that calomel, or calomel and boric acid, as above, are the best methods for general practitioners in towns and in the country, among the rich and poor, alike, for the reasons given above, and for the additional reason that calomel is a great antiseptic powder on the skin, keeping the entire surface free from urinous and fecal chafing; they are cheap, easily carried in the obstetrical bag, easily applied, and a teaspoonful is sufficient to supply a two weeks' course of dressing.

## Reviews.

---

LECTURES ON PHARMACOLOGY FOR PRACTITIONERS AND STUDENTS. By Prof. C. Binz. Translated from the Second German Edition by Peter W. Latham, A.M., M.D. Volume II.

London: New Sydenham Society, 1897.

Over a year ago we reviewed with much praise and commendation the first volume of this interesting work by the well known German pharmacologist, Professor Binz, of Bonn. The second volume is quite equal to the first in its quality and quantity. It contains about 450 octavo pages, and chapters from 17 to 31, concluding with a valuable table of the maximum doses which may be administered to adults (which is taken from the German Pharmacopœia), an Index of Remedies, and a list

of authors who have been referred to in the text. This volume consists in chapters upon Tannic Acid; the Vegetable Bitters and the Alkalies; the important Tonics and Alteratives, such as iron, phosphorus, and arsenic; the Mineral Astringents, as represented by bismuth, lead, and silver; and the Antisyphilitics, as represented by mercury and its preparations.

Succeeding chapters then deal with antiseptics, with quinine, with the recent antipyretics, with hydrocyanic acid, the inorganic and organic acids, emetics, purgatives and anthelmintics, oils and fats, irritants and caustics; and finally there is a chapter devoted to substances used for surgical and other purposes. This chapter, with a table of doses, index of remedies, and list of authors, already named, concludes the work.

Many pages are provided with copious bibliographies, which are limited, however, almost entirely to German literature. The book, as we pointed out in reviewing the first volume, is not a distinctly practical one upon therapeutics, and for that matter does not profess to be such. It is a brief summary of our pharmacological knowledge as Professor Binz finds it to-day.

We are sorry that in quoting from literature he has not consulted more authors outside of the German dominions. The volume as it stands to-day is a valuable and interesting one to the pharmacologist or the physician who is interested in the scientific side of therapeutics, but it is not one which the young physician will find particularly useful in the application of drugs to the treatment of disease. Naturally much attention is given by Professor Binz to the action of quinine upon the lower forms of life, and he takes pains to point out that many years before Laveran discovered the malarial organism he expressed a belief that the symptoms designated by the term "malarial fever" were produced by some form of bacteria.

EYE-STRAIN IN HEALTH AND DISEASE, WITH SPECIAL REFERENCE TO THE AMELIORATION OR CURE OF CHRONIC NERVOUS DERANGEMENTS WITHOUT THE AID OF DRUGS. By Ambrose L. Ranney, A.M., M.D. The F. A. Davis Co., Publishers, 1897.

The reviewer is somewhat embarrassed as to the nature of his sensations after the perusal of this book. If the frequently repeated and emphatic statements of the extraordinary and far-reaching effects of eye-strain, manifest or latent, real or artificial, can be accepted as the indubitable expression of the truth and the whole truth, the therapeutics of man-

diseases, both those usually classified as nervous and those that are not admitted by most practitioners as belonging to that category, must be revolutionized. Adherence to other doctrines of causation and the practise of medicine according to laws founded on pathology and experimental investigation become not only out of date but positively wrong.

The book does not admit of detailed analysis. Its defects or its virtues, whichever they are, are too glaring and fundamental, standing out conspicuously from the first page to the last, to make it profitable to criticize an argument or a conclusion here and there. It must be altogether praised or absolutely condemned. If the inorganic diseases discussed are reflex in their origin and continued by a maintenance of the cause, and if that cause lies in a maladjustment of the ocular focus or a want of equilibrium of the ocular muscles, the teaching of this book, too clearly enunciated to be misunderstood, must be accepted as the only rational method of therapeutics; but if we admit that these so-called functional diseases may arise from other causes, such as vicious inheritance, acquired predisposition, irregular habits of living, intemperance, indiscretions of various kinds, probably attended with microscopic anatomical changes, we must conclude that the author's studies in this special line were inaugurated by a mind predisposed to accept partial truths, and that his further researches have been pursued with an enthusiasm that has perverted his judgment and closed his eyes to all adverse opinions.

Lest the reviewer should be considered unfair in his criticism or biased in his opinion, a few extracts from the book are submitted: "Many diseases which are to-day commonly regarded as of bacterial origin owe their development, in my opinion, to some *underlying cause that has impaired the nervous functions.*" "I have never yet encountered a case of typical phthisis in which eye-strain did not exist as a factor (more or less potent, in my opinion, in causing and hastening its development)." "The so-called 'inherited predisposition' to certain diseases is unquestionably based, in many cases, upon some anomaly of the visual apparatus." His views on chorea are thus expressed: "I would assert that clinical experience had demonstrated most positively a *direct causal relationship between eye-strain and chorea;*" on sleeplessness thus: "*Clinical evidence goes to show that a large proportion of subjects affected with persistent in-*

*somnia of long standing suffer from some congenital defect of the eyes themselves or from an improper adjustment of the muscles that move the eyes.*" He believes many chronic and intractable intestinal disturbances are dependent upon eye-strain. Of twenty-six published cases of epilepsy he says: "Four have abandoned treatment almost from its beginning and should not be counted. Of the remaining twenty-two cases ten, or forty-five per cent., may be counted as well (seven being completely cured and three being practically cured); amelioration of the attacks has been afforded by eye-treatment in nine cases, or nearly forty-two per cent.; and no improvement has been observed in three cases—about thirteen per cent." (Among the complete cures is a case of twenty-four years' standing.) A number of cases of nervous prostration and insanity are reported as cured by adjustment of glasses and tenotomy of the eye muscles.

Ranney's methods of diagnosis are interesting. He lays great stress on the phorometer of Stevens, and accords secondary importance to the Maddox rod and strong spherical glass, both of which are in our opinion superior to the diplopia test because they do not displace but deform the image, and do not refract it onto regions of the retina that do not include the fovea; and he has omitted to mention the cobalt glass test, which, in operable cases, is to be strongly recommended for accuracy and for the saving of time. If a patient shows orthophoria at the first examination Ranney is not discouraged, but by a perseverance that can only be commended finally elicits muscular imbalance of degree high enough to warrant graduated tenotomies, one after another, until the muscles are restored (?) to equilibrium and the patient is cured. From an ophthalmic standpoint we might criticize the method of operation. Nowhere is advancement recommended. The only procedure advocated is graduated tenotomy, whereas the practise of other equally credible surgeons—that is, strengthening the weak rather than weakening the strong muscles—is ignored. Again, he fails to discuss the *raison d'être* for the anomalies other than to mention their congenital origin, but believes the entire fault is to be found in a too active muscle rather than a too great nerve stimulation to that muscle, or too little to its antagonist, and submits the reports of cures, supported by numerous testimonials, of the most serious disturbances of the nervous system by

dividing a few fibers, more or less, of one or more muscles at their ocular attachments!

Enough has been submitted to allow the reader to form an idea of the scope of this work and to warn him against accepting the method here advocated of treating the nervous diseases known as chorea, intestinal derangements, epilepsy, nervous prostration, and insanity. We acknowledge that Dr. Ranney has written an interesting book, but we would advise students of ophthalmology and practitioners whose opinions as to the importance of the causal connection of refractive and muscular anomalies of the eye to nervous disease are unformed, or whose familiarity with the subject is limited, that the doctrines taught can be accepted only with great caution; in fact, they are dangerous, and until verified by others had better be avoided.

H. F. H.

**SURGICAL HINTS: FOR THE SURGEON AND GENERAL PRACTITIONER.** By Howard Lilienthal, M.D.  
New York: International Journal of Surgery Co., 1897.

This little brochure of twenty-nine pages represents a number of serviceable cautions and suggestions founded on the writer's personal experiences in the practise of surgery. The hints are all valuable. Thus the advice is given not to operate for chronic tumor without having given antisyphilitic remedies for at least a week. Not to boil non-metallic sutures in soda solution commonly employed for the sterilization of instruments. Always to remove canary birds from a small room in which chloroform is to be administered. To pour vinegar upon the chloroform mask when the operation has been finished. Not to drive trocar and cannula through the skin, but make a small puncture through this structure. Always to open an abscess from without inward. To obliterate vacant spaces by suture. To avoid pinning dressings to the skin when the patient is under an anesthetic.

There is no attempt at consecutive teaching in these pages, and the entire work can be read in ten minutes. It is well worth the time spent upon it, since even the experienced surgeon will certainly find a number of valuable suggestions.

**A TEXT-BOOK OF DISEASES OF WOMEN.** By Charles B. Penrose, M.D., Ph.D. Illustrated.  
Philadelphia: W. B. Saunders, 1897.

This book is forcible and direct. Its author has the faculty of making his meaning perfectly clear in very few words. He has expressed himself dogmatically throughout, and has kept in view with singular fidelity the

purpose he had in publishing this work—i.e., to provide a book for the medical student. The book is to be commended without reservation not only to the student but to the general practitioner who wishes to have the latest and best modes of treatment explained with absolute clearness.

**TEXT-BOOK ON MENTAL DISEASES: FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE.** By Theodore H. Kellogg, A.M., M.D. Illustrated.  
New York: William Wood & Co., 1897.

This is a large volume of nearly 800 octavo pages, written by a medical man who has had wide experience in the management of the insane, chiefly in public and private asylums. It is dedicated to the editor of the *New York Medical Record*, Dr. George F. Shrady, in exceedingly complimentary terms.

The chapters deal with the history of insanity, the statistics, nosology, and etiology of insanity, the etiology, clinical progress and termination of mental diseases, and psychical and somatic symptomatology. The remaining chapters in Part I are devoted to the pathology of insanity, its diagnosis and prognosis, and the treatment of its various forms. In the second part of the book, which deals with special groups and typical forms of insanity, we have chapters upon insanity from organic arrests of development, the various constitutional neuropathic states and neuroses, and a study of the various states of depression, exaltation, mental weakness, and stupor. It may be gathered from this statement of the subjects which are dealt with by Dr. Kellogg that he has written an exhaustive work of considerable importance to neurologists, and particularly to physicians who see much of mental diseases.

**DIE NEUEN ARZNEIDROGEN AUS DEM PFLANZENREICHE.**  
Von Dr. Carl Hartwich.  
Berlin: Julius Springer, 1897.

Dr. Hartwich is, as many students of pharmacognosy are aware, the professor of this branch of pharmaceutical learning in the University of Zurich, and he has brought to the compilation of this book not only the result of much study, but in addition carefully arranged information from other workers in similar lines. Unlike many Continental authors he has not been content with a bibliographical search limited to German literature, but has culled his facts from every available source. With the object of making the work complete he has called to his aid the large manufacturing pharmacists of the world—such firms for example as Christy & Co. of London, and Parke, Davis & Co. of

Detroit and London—and he gives these sources of information full credit for the advantages offered him.

The arrangement of the volume closely resembles that usually followed in books upon medicinal plants. Each drug of great or little prominence is discussed in its alphabetical order, its derivation, varieties, and synonyms are given, and any peculiarities emphasized. Following this part is an addendum discussing matters not included in the main body of the text, and then there follows a most copious bibliographical index, which is perhaps the most useful part of the work. The next section is devoted to a botanical arrangement of the drugs considered; and finally we find an unusually complete index covering many pages. The volume is not intended for the practitioner of medicine, but will find a place in the library of every thorough student of materia medica or pharmacognosy.

### *LONDON LETTER.*

BY RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P.  
LOND.

With the approach of August therapeutics as a rule fade into obscurity and oblivion and remain outcast in the professional wilderness until the holidays are over. This week, however, is an exception to the annual custom, and is notable for a communication of first importance by Mr. Malcolm Morris and Dr. Whitfield of London on the use of Koch's tuberculin in cases of lupus vulgaris. The authors do not claim to bring forward more than some preliminary observations, which besides their intrinsic interest to the profession may also have the good effect of stimulating others to follow their lead. It is matter for congratulation that some one has been found who has not allowed the great expense of the material, nor the difficulty in obtaining a supply adequate either in quantity or quality, to stand in the way of a prompt investigation of its usefulness. As yet it is early to speak of cure, though the results obtained in the initial series of six cases are certainly of the most encouraging nature. Mr. Morris wisely declines to chant the pæan until he has made more extensive and prolonged observations, and until sufficient time has elapsed to assure him of the permanency of the good results that he is able to chronicle

up to date. One great merit of the new tuberculin is the very slight constitutional reaction to injections of ordinary size, and while larger doses do undoubtedly cause considerable constitutional disturbance, the reaction is of a comparatively transient character. This in itself may be regarded as a great advance on the old tuberculin. The results obtained by the authors have been summarized by them in their order of occurrence as: (1) a diminution of the surrounding halo of redness in those cases in which this had been present to a marked degree before the commencement of the treatment—in cases in which there were simply yellowish-brown nodules in a white scar, the injections produced no visible effect at this stage; (2) the next change noticed was a slight depression in the center of the nodules, leading to wrinkling, and later to desquamation of the cuticle; (3) steady healing of all ulcerated surfaces; and (4) slow subsidence of the previously permanent edema of the lips, ears, etc.—in some cases distinct shrinking and even complete disappearance of the nodules was observed. Lastly, in no single case even of the most obstinate kind was the slightest tendency to progress exhibited during the course of the treatment.

Of theories of chlorosis there is no end, and the latest addition to their number, by Lloyd Jones, Research Scholar of the British Medical Association, has at any rate the merit of originality. The term has been so loosely used to cover so many different conditions that, in the absence of any precise definition of what is denoted by the term, it is difficult to take issue with the theory. We certainly agree with the propagator of the new theory that the blood changes in cases clinically grouped as chlorosis do not consist wholly or even principally in diminution of hemoglobin, but that there is a general impoverishment, real or relative, of both hemoglobin and corpuscles. The examination of healthy blood in a large number of cases served to show that in women from puberty to the menopause some degree of general impoverishment of the blood is normal and natural, and has no counterpart in healthy male blood. The condition is evidenced in a greatly diminished specific gravity, this varying rather with the amount of hemoglobin than of corpuscles. Chlorosis, then, is a morbid exaggeration of a natural tendency. It is suggested that this normal decline is in some way associated with the child-bearing function of the female, and represents an anticipatory storage of

nutritive material to meet the increased demands of pregnancy; this is consistent with the well recognized tendency to "fill out," as it is termed, in the years following puberty. The natural corollary of these facts is that chlorotics should tend to greater fertility than other women, and this is asserted statistically to be true. It is to be hoped that society journals will not get wind of these views, or we may yet live to see chlorosis the fashionable craze of a London season. In any case physicians may look forward confidently to extensive practise in determining the specific gravity of female blood. Still what Dr. Jones gives to the profession with one hand he takes away with the other, in his observation of the concurrence of light complexion with low specific gravity and high fertility, as this is a decision that requires no specialist opinion. Dr. Jones ingeniously meets the objection that chlorosis is not a condition exclusively confined to women by suggesting that the low specific gravity in women is due to increase of plasma, while the chlorotic condition occasionally found in the male is due to actual diminution of plasma, so that the blood becomes actually heavy, as he finds it to be. In his treatment of chlorosis Dr. Jones has nothing more original than iron to suggest. We sincerely hope that his further investigations will fail to establish, as he surmises, an autointoxication from the uterus or ovaries, as we have no wish to see oophorectomy or hysterectomy placed on a rational basis in the scientific treatment of chlorosis.

At a recent meeting of the Edinburgh Medico-Chirurgical Society an interesting paper was read on picric acid as a primary dressing for burns. We confess to a feeling of thankfulness that, however satisfactory the method may be, it had not come into use in our student days. We are assured, however, that the hands need suffer no staining, if smeared with vaselin before dabbling in picric acid, and if washed in alcohol afterwards. Certainly we cannot claim hitherto to have discovered any agent that fulfils the primary requirements of a suitable dressing for burns. The method described by Mr. Miles consists of a preliminary cleansing of the part with a weak carbolic lotion, followed by the application of surgical lint soaked in a saturated solution of picric acid (picric acid,  $1\frac{1}{2}$  drachms; absolute alcohol, 3 ounces; water to 40 ounces), with a covering of wool and a many-tailed bandage. He claims for this method that it is painless, but we observe

that chloroform is administered during the dressing, which detracts somewhat from the anodyne virtues of picric acid; also that it is a most efficient antiseptic, so that there is but little discharge and no necessity for frequent change of dressings. Among other minor advantages he regards the astringent nature of picric acid as valuable in allaying inflammation, and in stimulating the growth of epithelium.

The Inebriates' Legislation Committee of the British Medical Association has during the past year been making strenuous efforts to procure improved means of dealing with habitual drunkards. The Government has been urged to invest properly constituted authorities with the power of compulsorily secluding such inebriates, so that they may be brought under some sort of curative régime, in place of running the gauntlet of the police courts. We are glad to see that the Government has expressed an intention of dealing with the matter in the course of this session, but we wish there were not the qualifying condition "if time permits." The committee recommended that such a bill should include: (1) The compulsory therapeutic detention of habitual drunkards after a judicial process, on sworn testimony, and with every possible safeguard for the liberty of the subject; (2) the establishment and management of special homes for inebriates for the poorest, for criminal and non-criminal inebriate offenders; (3) the inclusion of intoxication by any narcotic in the term "habitual drunkenness;" (4) the appearance of voluntary applicants for curative detention before one justice instead of two justices as at present, or before some authorized official; (5) magisterial discretion to award a term of curative restraint in a reformatory or hospital instead of a term of imprisonment in a jail. It is sincerely to be hoped that the Government may be able to enforce all these recommendations, so that the habitual drunkard may be placed into the category of insanity, to which he practically belongs. The existing system under which patients voluntarily place themselves within the control of a licensed Retreat has worked admirably, and has fully justified its compulsory extension to all inebriates. We fear that objections may be raised on the score of expense, which must of necessity be increased in substituting a six months' detention under curative treatment for the existing short period of incarceration.

We learn with no small satisfaction that the

interested agitators who sought to transform the British Medical Association into a gigantic machine for medical defense have failed of their purpose. We can scarcely conceive a more preposterous suggestion than that the articles of association, under which existing members enlisted, should be altered so as to precipitate the whole body of members into every petty squabble of each and every member. Nor have we any sympathy for the ingenious sophistry that would argue such a proceeding to be consistent with the interests and honor of the medical profession. It is, however, matter for regret that the margin of votes taken from the branches on the proposition was not of a more substantial character, as the agitation is only too likely to be renewed at an early date. There can, however, be little doubt that compliance would lead to the withdrawal of very many members from the Association—those who have no palate for trades-unionism in medicine.

There is an element of comedy in the attitude which the profession has adopted with regard to the cognate question of hospital reform. A month or more ago a representative meeting of leading metropolitan practitioners denounced the efforts of the Charity Organization Society to form a central hospital board for the general control of medical charities. The antagonism, however, was directed not so much against a central board as such, as against the effective representation of the Charity Organization Society on the board. Simultaneously the Medical Charities Committee of the British Medical Association, which is the mouthpiece of almost identically the same body of medical opinion, expresses especial satisfaction at the action of the Charity Organization Society. And as each meeting has in succession memorialized the Prince of Wales in furtherance of its own wishes, we should say that probably some doubt exists in the mind of His Royal Highness as to what the profession wants or thinks it wants. The comparative failure of the Prince of Wales Hospital Fund has done much to cool the ardor of the more enthusiastic reformers.

The third volume of Clifford Allbutt's "System of Medicine" has just come to hand. It deals with certain General Diseases of Obscure Causation, Diseases of Alimentation and Excretion, and Diseases of the Stomach, Peritoneum, and Bowels. At present we have not been able to investigate the new volume in more than a most cursory manner, but our

first impression suggests that it is quite equal to its predecessors. An article that will certainly attract general attention is that by Rose Bradford on the General Pathology of Secretion, a subject on which he speaks pre-eminently *ex cathedra*. The article on Gout by Sir William Roberts possesses all the graphic and picturesque literary features that lend so much attractiveness to his writings, while that on Rickets, by Cheadle, is obviously from the pen of a master-hand. In unpleasant contrast to these are the altogether scanty and inadequate paragraphs on diseases of such special interest as osteomalacia, osteitis deformans, acromegaly, and hypertrophic pulmonary osteo-arthritis, by Bowlby. In the chapters on diseases of the bowels will be found an exhaustive article by Treves on Perityphlitis, for which he discards the uncouth name "appendicitis," though fully recognizing the paramount part played by the appendix in the disorder.

Another excellent book, by Lauder Brunton, on the "Action of Medicines," has just been published. It represents in substance, if not in form, the series of lectures to students at St. Bartholomew's on Pharmacology and Therapeutics, and we congratulate them on the good fare provided for them. Throughout the entire volume we notice a judicious blending of fancy with fact, and that happy coalescence of matter with style which makes a work classical and of something more than ephemeral value.

The "invasion" of the medical profession by womenkind spreads apace. At a recent prize-giving ceremony at the Royal Free Hospital, to which is affiliated the London School of Medicine for Women, the Dean—Mrs. Garrett Anderson—announced that the new entries for the year amounted to sixty-two students, making the third largest entry of any metropolitan hospital. This rapid increase contrasts curiously with the notable decrease in the number of male students in the last few years, since the curriculum has been extended to five years. The existing laboratories are no longer sufficient to meet the requirements of this great influx of students, and extensive building is already in progress in anticipation of the October entry. The new buildings are designed on a scale that will compare favorably with any of the existing medical schools. The Conjoint Examination Board still decline to admit lady students to their examinations, but there are not wanting signs of yielding even in this quarter.

### THE VALUE OF KOLA AS A STIMULANT OF THE PARTURIENT UTERUS.

BY H. A. HARE, M.D.,

Professor of Therapeutics and Materia Medica, Jefferson Medical College, Philadelphia.

The drugs that act as direct stimulants to the uterine muscle at about the time of full term, or upon the nervous centers in the spinal cord which control uterine contractions, are very few. Probably ergot is the only one possessing a well defined action of this character. The profession has, however, for many years recognized the fact that

quinine might be used for the purpose of supporting uterine contractions after they had normally originated, or for restoring them after they had been arrested by inertia or other cause. That this drug quinine has not, however, any marked power over the uterus or its nerve supply, and acts almost entirely by a general stimulating effect on the nervous system, seems likely, from our knowledge of its general action and from the results reached in a collective investigation recently published by me in this journal.\*

Some months since Dr. Gundrum, of California, wrote to the THERAPEUTIC GAZETTE

\* "The Value of Quinine as an Oxytocic," THERAPEUTIC GAZETTE.

suggesting the use of kola in uterine inertia. I therefore obtained from Parke, Davis & Co. some of the fluid extract of this drug and placed it in the hands of Dr. B. C. Hirst, the Professor of Obstetrics in the University of Pennsylvania, for trial in the maternity wards of that institution; in the hands of Dr. E. P. Davis, Clinical Professor of Obstetrics in the Jefferson Medical College, for trial in the Jefferson Maternity; and in the hands of Dr. R. C. Norris, for use in the Preston Retreat. The conclusions reached by these gentlemen are found in the following reports:

DEAR DOCTOR:—Under Dr. Hirst's direction, I have used fluid extract of kola in a number of cases during labor at the Maternity. The following results were found, when the fluid extract was administered in thirty-minim doses (one dose):

1. Pains are more frequent and severe, in several cases quite apparent to the women themselves.
2. The women seem much more excitable and demonstrative under the influence of the kola.
3. In several cases an unusual amount of bleeding followed the administration of the drug. In one case there was an adherent placenta. Whether the two last named factors were accidental or not requires more clinical evidence to disprove or prove.

The kola was given both to primiparæ and multiparæ, but only when a natural relaxation occurred in the character and frequency of pains—in other words, when an indication arose for the use of a stimulant to uterine contraction. In all cases only a single dose of thirty minims was given (P. D. & Co.).

Respectfully yours,

WILLIAM SCHLEIF.

N. B.—In only one case was there no effect whatever.

Dr. E. P. Davis sent the following notes:

"In two cases kola was given after labor had begun, and it is impossible to determine what part was played by the drug.

"In five cases from one to two and a half ounces was given each patient in doses of half a drachm every three hours during the day for several days previous to the beginning of labor. In these cases the commencement of labor did not seem to be hastened by the use of the drug, but after pains had once begun they seemed to be stronger, more regular, and the force no doubt continued longer under the use of the drug. In all cases the pains continued strong from the beginning of first stage until the end of labor, there being no cessation in any instance.

"In one case pains began two hours after the administration of kola was begun. The pains here continued strong and regular to the end.

"In one case the first stage began in the evening. Pains gradually grew stronger, although expulsion was impossible on account of faulty rotation (occip.-post.). Pains re-

mained strong until child was extracted. Even under an anesthetic pains continued very marked. This patient received kola for several days before labor in half-drachm doses every three hours.

"In two cases kola was given for two days, when labor apparently began. In a few hours, however, the pains ceased, and have not returned at this writing.

"In one case pains came on, but ceased soon after, and it finally became necessary to induce labor."

Dr. Norris replies as follows:

"I have used the fluid extract of kola in doses of twenty drops, repeated once in one hour, in seven cases of uterine inertia. The first case, a multipara, had very fair uterine contractions for several hours, when they ceased almost entirely. The first stage of labor was about completed. The doses of kola were followed by strong pains and effective contractions. The labor was speedily terminated in a natural manner. I have repeatedly used forceps in similar cases.

"The second case, a primigravida aged thirty, became exhausted toward the close of labor, and the pains were weak and infrequent. Two doses of kola increased the strength, but not so markedly as in the first instance. The other five cases were, I believe, stimulated."

---

#### THE TREATMENT OF PUS CASES IN OPERATING FOR APPENDICITIS.\*

By M. M. JOHNSON, B.PH., M.D.,  
Hartford, Conn.

A great diversity of opinion exists as to the technique of dealing with pus cases when operating for appendicitis—especially as to what shall be done with the appendix. In this class of highly infectious cases, including gangrene, perforation, and pus, the writer has had an interesting and highly satisfactory experience. When the diagnosis of an abscess is made, the same care that would be taken in an aseptic case is employed to thoroughly prepare the patient, hands of the operator, and instruments. Pyrozone and an ample supply of saline solution are at hand.

An incision two or three inches in length is made over the most prominent point of the tumor; when the abdomen is entered offensive pus flows out. The operator holds the in-

---

\* Read before the Connecticut State Medical Society, May 27, 1897.

cision wide open, while the assistant pours the saline solution into the abscess cavity with a pitcher (the cleanest, cheapest, and best irrigator ever used). Pyrozone is then poured into the abscess and washed out with the saline solution. This process is continued until the abscess cavity is thoroughly disinfected. The appendix is usually easily found, either embedded in an infectious exudate in the abscess cavity or situated in the abscess wall, perforated and gangrenous.

The question is, What shall be done with the appendix, especially when it forms a part of the abscess wall? Our highest surgical authority is overwhelmingly in favor of not removing the appendix, for fear of infecting the general peritoneal cavity. On the contrary, I have removed the appendix in every instance, without infecting the peritoneum. I have always found it a safe procedure, if the abscess cavity is thoroughly *disinfected* before the walls are broken through.

When we have opened and disinfected the first abscess, our work has only begun. We must bear in mind the frequency with which multiple abscesses occur, and continue to break up the adhesions until we have opened one abscess after another, disinfecting as we go. It is evident that to stop with the opening and draining of the first abscess, without touching the others, leaves the patient in about as dangerous a condition as he would have been if no operation were performed. There is no doubt that many deaths occur from a general septicemia, resulting from unopened abscesses as centers of infection. If I found that this method of operating was followed by a general infection of the peritoneal cavity, resulting in death in a large percentage of my cases, I would certainly change my technique; but as long as my percentage is good, and my pus cases are making excellent recoveries, I am justified in holding to this method.

I will relate briefly a case which will illustrate this phase of the subject:

October 5, 1895, I saw E. B., aged fifty-seven. There was a well marked tumor in the right inguinal region, which the attending physician said had been there one week. It was evident that a large abscess had formed, as the result of a perforated appendix. October 6, patient was taken to Water-nook Sanitarium and properly prepared. The next morning the operation was performed. An incision two and a half inches long was made over the most prominent point of the tumor. The cæcum was found drawn well

down into the iliac fossa; the attachment of the appendix was covered with a firmly adherent omentum. The adhesions were broken up and the omentum removed, when was disclosed the fact that the appendix entered the pus sac. Pressure with the finger at this point perforated the abscess wall, and a pint or more of offensive pus escaped. The cavity was thoroughly disinfected with pyrozone, and washed out with the saline solution.

The wall of the pus sac was built around the point of perforation in the appendix; these adhesions were broken up and the appendix freed from the wall of the pus sac. The distal end of the appendix was found adherent to the promontory of the sacrum; this attachment was separated, and the gangrenous, perforated appendix removed. Continuing, two more pus cavities were opened and thoroughly disinfected. The wick drainage was inserted, the incision partially closed, and the dressing applied.

If there is danger of peritoneal infection as a result of breaking up adhesions and stripping the appendix out of the abscess wall, this case afforded all the conditions necessary. Theoretically, this patient should have died from a general septic peritonitis in forty-eight hours. The fact is the patient made an uneventful recovery, and returned home in three weeks from the day of the operation, and has enjoyed good health and worked regularly since.

In the case which I will now relate we have all the conditions of the last one, plus a general septic peritonitis and acute gastritis. As this case made a good recovery, it is worthy of consideration.

On the evening of October 3 I saw N. M., who during the day had suffered from colicky pains, and had vomited. There was no localization of the pain; the pulse was high. Morphine was administered, and he improved next evening, although severe attacks recurred. The second day the pain became localized in the cæcal region; there was no general tympany; temperature in the rectum 102°; pulse 80. An ice-bag was applied locally, and morphine given internally; next day a calomel and salts purge. There was severe pain, but no muscular reaction on pressure, or tympany, but continued vomiting, which lasted until the time of the operation. Temperature per rectum varied between 101° to 102°; the pulse was low and quick.

On the sixth day Dr. Johnson saw the case and agreed the symptoms were not pressing.

October 10 temperature rose to  $103^{\circ}$ , pulse 100; attacks of pain became more frequent. The ice-bag was continued and another cathartic given. After a second consultation with Dr. Johnson an operation was decided on, despite the objections of the family.

Patient was removed to Watnook Sanitarium on October 11, where he arrived in a collapsed state. It was with difficulty that the rapid pulse could be distinguished. Stimulants and black coffee were administered per rectum, and strychnine hypodermically, as he vomited everything administered by the stomach, owing to acute gastritis. It was owing to this treatment that the patient by the next morning got into a condition to stand an operation, which could be deferred no longer.

He went under ether easily, and Dr. Johnson opened the abdomen. After considerable search among the exudate he uncovered a pus cavity. The adhesions were broken up with the utmost care. During the exploration a number of pus cavities were disclosed and emptied, which seemed to radiate in different directions and showed no communications. On further search, deep in the pelvic cavity, the remains of the appendix were discovered; and after further manipulation a flat membrane, the remains of the appendix, was brought to view, which showed a ragged opening and had been adherent to the cæcum. The free wall was ulcerated away entirely, and a patch of the attached wall was also gone; the exudate was very extensive. The wound was partially closed after thorough disinfection.

At the time of the operation the patient was suffering from acute gastritis and general septic peritonitis, besides the appendicular condition just disclosed. Three days after the operation the cæcum perforated and emitted much fecal matter. A profuse flow of yellow serum continued from the wound during the exudative stage of the peritonitis. No intrusion was made into the peritoneal cavity beyond what was necessary to remove the appendix and open the surrounding pus sacs. Frequent irrigations and free drainage were continued. The perforation closed spontaneously. The patient made a good recovery and went home six weeks after the operation. The final good result in this case was due to the thoroughness with which the multiple pus sacs were opened and drained, and the infectious appendix removed.

The expression of the opinions of our most eminent surgeons (*Annals of Surgery*, June,

1896) on the question of removing the appendix in pus cases is strongly against it. McBurney says: "There are certainly some cases, not few in number, in which the appendix is so deeply embedded in the wall of the abscess, or so difficult to define at all, that to insist upon its discovery and complete removal would be to incur quite unjustifiable risk."

Dr. Bull says, in cases where the abscess is distinctly circumscribed, with firm walls, containing several ounces of pus, he does not attempt to remove the appendix.

Dr. Senn says it has been his habit for years, in cases of acute appendicitis with extensive suppuration, to simply incise, disinfect, and drain the abscess. He considers a further search for the appendix hazardous, as it often results in a fatal septic peritonitis.

Drs. Halsted and Richardson concur in the opinions expressed. In the very able article by Drs. A. J. McCosh and Forbes Hawkes (in the May number of the *American Journal of the Medical Sciences*) it is stated that in twenty-seven cases of localized abscess the appendix was removed in thirteen cases, not removed in fourteen cases. The indications for not removing the appendix are when the appendix is not clearly seen or felt in the wound after evacuating the pus. Yet in the same paragraph it is stated that when the abscess cavity is thoroughly disinfected with 1:1000 bichloride solution, should a small opening be made into the peritoneal cavity the danger of infecting the general peritoneal cavity is not great, provided gauze drainage is used. Ten cases are then cited where the appendix was removed (in simple abscess) and the peritoneal cavity opened in each case, and all recovered.

The reason for these recoveries is evident, when it is clearly stated that the abscess cavity was thoroughly cleansed with a 1:1000 solution of bichloride. If these ten cases were successful, why not give the fourteen cases where operation was not performed a chance for recovery by a similar treatment?

In the same article it is also stated that in eleven cases of general septic peritonitis nine were operated upon, two not operated upon. Of the nine operated upon six died, three recovered; mortality,  $66\frac{2}{3}$  per cent.

In all these opinions quoted no mention is made of the condition of multiple abscesses. The whole discussion is confined to the opening and draining of one abscess, and leaving the appendix in. A large death-rate must

result from septicemia, caused by the multiple abscesses as centers of infection.

The death-rate in this class of cases will be greatly reduced when a more thorough operative technique is adopted. We are dealing with a pyemic condition, with the gangrenous appendix as the primary cause of infection. It should be removed and all the pus centers evacuated and thoroughly disinfected. Your patient is then safe.

While I believe in free drainage, yet I never make my incision long enough to allow the intestines to escape from the abdominal cavity, but break up adhesions, open abscesses, and remove the appendix, manipulating the intestines as little as possible.

The practice of McCosh and Hawkes, of making the incision as long as possible, allowing the intestines to come out in mass into a towel, with the necessary manipulating and handling in the process of washing and returning with hands but shortly before covered with pus from the abscess, must be a direct method of spreading infection, and the whole procedure must be an unnecessary shock to the nervous system.

In the after treatment the wound is left partially open and is thoroughly irrigated with the saline solution, as long as pus is present. The wick drainage is inserted for twenty-four hours; after this, rubber tubing, with scrim gauze drawn through it, is continued until the wound granulates from the bottom, so that drainage is unnecessary. The wound is cleansed with pyrozone for three or four days; it is then discontinued, as it destroys granulation. No form of opium is ever used following the operation. Strychnine is administered hypodermically for the first three days, and then given internally. The patient is liberally nourished with animal food.

Out of a total of sixty-four pus cases there were sixty recoveries and four deaths.

*THE RATIONAL TREATMENT OF THE  
CONSTITUTIONAL FACTOR IN THE  
CAUSATION OF HAY-FEVER.*

---

BY CHARLES PREVOST GRAYSON, M.D.,  
Lecturer on Laryngology and Rhinology in the Medical  
Department of the University of Pennsylvania;  
Chief of Department for Diseases of Throat  
and Nose, University Hospital.

---

So long as almost all the laity and a large proportion of medical men continue to regard hay-fever as incurable; so long as a number of general practitioners persist in the

attempt to cure it solely through the agency of drugs, and a number of rhino-laryngologists seek to attain the same end solely through intranasal medication or surgery; so long, in fine, as the ultimate nature of the disease is imperfectly understood or even regarded with indifference—so long will there be ample justification for brief papers that shall not only insist that the disease can almost invariably be cured, but shall show how this may be accomplished.

A moment's reference to the several trivial theories that attempt to explain the evolution of the disease cannot be avoided; but ferments, micro-organisms, acid nasal secretions, and the like, are all idle speculations that add nothing whatever of value to our means of treating hay-fever. They merely hang upon the skirts of what we positively know of the malady, and serve only to distract attention from the broad therapeutic principles that must underlie its successful management. What we do know of it can be epitomized in a few words. Three factors compose the causative combination; of these, two—the existence of an external irritant and of some intranasal abnormality—are accepted without discussion. As to the third, however, there is considerable diversity of opinion. That it is constitutional or diathetic is generally believed, but whether it is sufficiently well defined to be given a specific name, such as "the neurotic temperament" or the "gouty or uric acid diathesis," or some other equally distinctive title, is still far from being settled. The very fact that opinions concerning it differ so widely as the two suggested titles indicate is evidence of the want of unanimity concerning its precise nature. As a matter of fact, however, names in a case of this kind are merely ornamental, and are, indeed, objectionable, for the reason that they tend to discourage separate and searching study of each case. Even if we grant that a certain number of hay-fever sufferers are unquestionably people of "neurotic temperament," while others, without being at all neurotic, are of a certainty gouty, can we not profitably look beneath these titles and recognize the fact that they designate dyscrasiæ, which are merely different offshoots from a parent weed that is rooted in defective nutrition? Is it not, therefore, to this primary departure from normal processes that we should address our corrective measures? Of what use is it to administer to the neurotic individual the most potent of nervines, or to the gouty patient the best of the antilithics, if underlying

both of these conditions there is a cause upon which none of these remedies exerts a noticeable influence?

There is no need to analyze the expression "defective nutrition" further than to state that it is meant to include all the phenomena of metabolism—constructive, destructive, and eliminative. Disturbance of one of these means disturbance of all, and, as a final observation upon this subject, we may note the fact that with continued absorption of toxic materials from the intestinal tube, or with persistent incomplete elimination of the products of sub-oxidation, it is only a question of time when autotoxemia will provide us with any of the functional neuroses from hay-fever and asthma to chorea and epilepsy.

With this broad conception of the constitutional factor that shares in the genesis of hay-fever, its rational treatment will evidently demand far more than a mere juggle with drugs, be this ever so skilful. The end to be attained is the removal and the checking of further production of every toxic body that can so enfeeble the nerve centers as to render possible this annual vasomotor paresis that affects the intranasal circulation. The merely eliminative portion of this procedure is not a matter of great difficulty, but when we grapple with the problem of preventing further contamination of the blood current we find that it is no trifling task that we have undertaken. And this is so because our success so largely depends upon the intelligence of the patient and the fidelity with which he cooperates with us. To secure this cooperation, and to retain it until the victory is gained, requires both tact and firmness. A sensible patient will not regard it as an evidence of weakness if we confess at the outset our inability to conquer the disease single-handed; and if he be well impressed with a sense of his own responsibility in the winning of the battle, he will seldom have to be coaxed or threatened in order that he shall do his share. I regard it as a means of saving time, temper and reputation to have a clear understanding with the patient, before the first blow is struck, as to what we will expect of him. The very essential restoration of the nose to a state of health is exclusively our own affair, and we can effect that unaided; but when it comes to restoring the patient's nutritive processes to functional perfection, to rehabilitating his more or less dilapidated nervous system, he must join with us in the struggle that it involves. The main battle-ground is to be his own gastro-intestinal tract, and, as he is to be

the one sentinel throughout the conflict, much depends upon his constant vigilance and his strict obedience to orders.

One more word regarding the character of our enemy and we will abandon this figurative strain and descend to formal English. It is a host of hygienic blunders and, perhaps, wilful bad habits that we are to meet and overcome—self-indulgence (a term covering a multitude of sins), irregularities connected with the patient's hours for meals, for work, rest, and play, indiscretions of diet, lack of exercise, objectionable fancies in matters of clothing and bathing, and, finally, vicious excesses—alcoholic, narcotic, or sexual. All these make quite a formidable array, and they are to be subdued not by any single brilliant bit of strategy, but only by a prolonged and unrelenting struggle that requires immense patience and determination. In considering the ways and means, I make it a rule in my lectures at the University of Pennsylvania to enter quite thoroughly into details,\* but in these columns this is uncalled for, and I have only to emphasize certain points that I regard of special interest and importance.

The accurate adaptation of the diet to any inherited or acquired morbid state that the patient presents is one of the first essentials. It is not enough merely to reduce the starches and sweets if he be neurotic, or the nitrogenous foods if he be gouty—a shallow routine would dictate that much; but the age, the sex, the occupation, the whole environment of the patient must be separately studied and provided for in the dietary scheme.

In the closest possible association with the regulation of food is that of exercise. By the majority of physicians scarcely anything is prescribed with less intelligence, with less apprehension of its possibilities for good or evil, than this agent. Judiciously advised, with careful reference to the condition and needs of the patient, it is worth all the drugs in the Pharmacopœia. Iron is, indeed, a veritable specific for these cases of nervous and muscular asthenia, but it should be prescribed in the form of dumb-bells. Is it not an egregious folly to prefer the temporary and deceptive benefits of strychnine to the permanent and real ones that attend the proper use of the muscles? Is the passive cutaneous leakage that transpires in the hot-air chamber of a Turkish bath establishment to be compared in therapeutic value to the

\**University Medical Magazine*, July, 1896.

natural and healthful stimulation of the sweat glands that accompanies active exercise? I believe in nothing more firmly than that if a man takes care of his muscles his nerves will take care of themselves. And yet there is no closing our eyes to the fact that, to the average man, exercise is distasteful, is hard work, yea, even drudgery. It requires all the eloquence we possess to convince him, first, of its necessity, and then to persuade him to adopt and adhere to it. We are not, therefore, to be content with lightly telling him to "take a little more exercise," to walk where now he rides, or, in these days, to buy himself a wheel—and then to leave the manner of its use to his own unenlightened discretion. The more stress we lay on this portion of the treatment, the more explicit we are in our instructions concerning it, the more will the patient be impressed with its importance and the necessity for doing what he is told. In brief, then, it is in the skilful blending of diet and exercise, and their application in proper proportions to each of these patients, that we have the one rational and reliable method of removing the constitutional factor that is so active in the causation of hay fever. Within a reasonable time the digestive tract is restored to a state of sanitary purity, general nutrition is established upon a firm foundation, and the previously unstable nervous system, steadied and invigorated, is enabled to resist such disturbing influences as once proceeded from the contact of atmospheric irritants with the hyperesthetic pituitary membrane; the vasomotor centers resume their domination over the nasal erectile structures, and the distressing phenomena of hay fever are known no more.

Of course, that which I have written here concerning diet and exercise applies with equal force to both sexes and all ages. Certain modifications, it goes without saying, are to be made with respect to differences in sex, age, and occupation; but the essential idea is to put the patient upon a course of strict training that will bring out all his capacity for self-denial and self-help, that will effect a most salutary change in his whole *morale*, and that will so completely remove the hyperesthesia of the nasal sensory nerves as to make them contemptuously indifferent to, even unconscious of, a species of irritant that once sufficed to throw them into a state of violent commotion. There is nothing brilliant, it is to be confessed, about this method of removing the constitutional factor, but for what it lacks in brilliancy it more than makes

amends in certainty. It is, often enough, slow and tedious, but to patients possessed of grit and determination it brings a sure reward. It penetrates to and combats the very beginnings of pathogenesis, and with this fact in mind we can scarcely be over-confident in anticipating and prognosticating success.

*SENECIO AUREUS AS A HEMOSTATIC IN  
CAPILLARY HEMORRHAGE.*

---

BY F. GUNDRUM, M.D.,  
Sacramento, Calif.

---

In the spring of 1871 I was consulted by a gentleman whose case is as follows:

CASE I.—Mr. B., aged forty; native born. His occupation up to ten years ago was that of a farmer; since then he has followed the carpenter's trade. His health had always been good. Has never used alcohol in any form.

About six months ago he was taken with a dull pain in the region of the left kidney, which was soon followed by red-looking urine. He consulted his regular physician, who diagnosed it hematuria. He was treated for four months, but getting no better a second physician was called into the case, and the two treated him for two months longer, without the least benefit; on the contrary, he was losing more blood and had lost much of his strength. For the last two months he had been unable to do any kind of work. On a careful examination I reached the same conclusion as to the nature of his difficulty as his previous medical attendants, viz., hematuria. I put him to bed for a while, gave him all the remedies recommended by the text-books and current medical literature—in little, moderate, and big doses—with the same success that my predecessors had. If any change had taken place during my six weeks' treatment it was certainly for the worse.

About this time a neighboring physician made me a friendly call, and I related the case to him and asked him if he knew of any remedy that was likely to help my patient, telling him all the remedies I had given him. He said: "Put your patient on a teaspoonful of fluid extract *senecio aureus* three times a day, and you will soon clear up his urine." I knew nothing of the remedy or its therapeutic virtues, but as I had got to the end of my rope I was willing to try it on my patient.

All other medication was stopped, and the patient was given the remedy. In two days

his urine was as clear as spring water; in other words, there was not a red corpuscle to be found. The remedy was continued for a week and then discontinued. The patient, under tonics (including iron), soon recovered his strength and went to work. In ten months hematuria again started, but was again arrested, and has not since returned.

CASE II.—I was asked to take charge of Mrs. D. during her first confinement. She is of medium height, rather spare in build, and while she has never been strong, she has never had occasion to consult a physician. During the first days of the seventh month of her pregnancy I examined her urine, and found a considerable quantity of albumen. She was put on the proper diet and remedies and hygienic conditions. As her term approached the amount of albumen increased. She was finally put on pure milk diet; the skin was stimulated, the bowels kept free, and she was kept in fair condition. She was taken in labor pains April 7, and had a hard, tedious, but natural delivery. Some ominous symptoms presented themselves and I lowered the reflexes with small doses of morphine and atropine, chloral, and inhalations of chloroform. Twelve hours after delivery she had a convulsion, and two more before I reached the house—in less than half an hour—and had a fourth as I stepped to the bedside.

On the fourth day after confinement the urine was free from albumen; on the tenth day patient was out of bed, looking fairly well and feeling comfortable. The flow of milk was abundant, and she had a fairly good appetite.

On the twentieth day after her accouchement the husband brought to me about seven ounces of urine, the color of coffee-grounds, stating it was all the patient had passed since 6 P.M. the day before—making the total amount of twelve hours' secretion. I visited the patient and looked into her condition. No particular cause could be found, and thinking that the *plasmodium malariae* might be at the bottom of the pronounced hemoglobinuria I put the patient on ample doses of quinine for twenty four hours. The quinine brought no improvement, and the urine diminished in quantity and deepened in color. Sodium acetate and digitalis infusion were given, which increased the flow of urine some, but had no effect on the hemoglobinuria.

The patient now commenced to complain of a heavy pain in the region of the left kidney, and in two days we had hematuria added

to the hemoglobinuria, the patient in the meantime becoming very anemic and discouraged. She was kept in bed between blankets, the action of the skin was encouraged, and a strict dietary carried out. I ordered fluid extract ergot, with ten drops tincture of opium, three times a day, and liquor ferri perchloridi three minims, in egg albumen, as suggested by Ewald, three times a day. After effecting nothing in four days with this treatment—the hematuria having steadily increased—the patient was put on the fluid extract of senecio once in four hours. In twenty-four hours the urine was *almost* free from blood-corpuscles, but still showed a perceptible amount of hemoglobin. The senecio was reduced to one drachm three times a day, and iron, quinine and strychnine ordered in proper doses three times a day. Patient gradually improved, and left for her mother's home five weeks afterwards.

In order to show that the remedy has no special or selective influence in hemorrhage of the kidneys, I will give the following two cases:

CASE III.—Mrs. S., aged thirty-six; small of stature; brunette. She had hemoptysis several years ago. Her health has not been good for the last year, having suffered considerably from indigestion. She was taken with spitting of blood on the night of November 6, 1896. I was called about 8 A.M. and found her expectorating a mouthful of capillary blood about once in five or six minutes. She had already taken the usual dose of common salt without effect. She was placed in a semi-prone position in bed, and bags of hot water placed to the feet; the dietary was carefully selected, and opium and ergot ordered. After two days, no improvement having taken place, the remedies were suspended and the oil of erigeron ordered, five minims once in three hours. The bleeding diminished under this remedy, but on the third day it became as bad or worse than ever. I now determined to try the senecio in hemoptysis. I ordered a teaspoonful once in four hours, to be omitted during the night if she slept. There was no more fresh blood after twenty hours' administration of the remedy. The patient died since from acute pulmonary tuberculosis.

CASE IV.—Mrs. J., aged twenty-four; married two years. She commenced to menstruate at fifteen. Menses have always lasted from five to seven days and rather profuse, attended with pain and a heavy, full feeling in the pelvis. Since her marriage she has

become worse in this regard; she now menstruates from seven to ten days, losing twice the amount of blood she did before her marriage.

One to two days before the menstrual period the pain in the back and the heavy, full feeling in the pelvis is experienced, and a mucous, tenacious discharge from the vagina shows itself; then the sanguinous flow sets in quite profusely, attended with considerable pain. After the first two days the pain disappears to a great extent.

Having lost considerable strength and her color, she thought it was time to consult a physician. On examination nothing was found, except the uterus seemed to be somewhat congested, and a slight glairy discharge from the cervix. I ordered ferri et quin. cit. in five-grain doses three times a day, to be stopped three days before the menses were to make their appearance. She was then to take a teaspoonful of the fluid extract of senecio aureus four times a day and to continue it during the whole flowing period. The remedy very much controlled the menorrhagia the first time, the period lasting barely seven days, and the quantity scarcely exceeding that which she lost while single. She continued the senecio every month for four months at each period, when the menstrual flow lasted about five days, and the quantity not above normal.

My friend Dr. B. had used the remedy for many years, and prized it above all others "in bleeding from internal organs." I have used it since 1871 and consider it the most valuable remedial agent in parenchymatous hemorrhage we possess. As it is not an astringent it must bring about the benign results by acting on the vasomotor nerves.

I have spoken with many medical practitioners and never found one that knew of its hemostatic action; hence this short contribution. In conclusion I may say that I sometimes give it in two-drachm doses if one does not suffice.

2011 T STREET.

#### THE POST-OPERATIVE TREATMENT OF SURGICAL CASES.

BY THOS. LEIDY RHODES, M.D.,

Assistant in the Surgical Clinic, Jefferson Hospital, Philadelphia.

It too often happens in our medical schools that on leaving the operating table the patient passes completely out of existence so far as his relation with the students is con-

cerned. It likewise happens that when in the course of a few years these students assume charge of patients that have been operated upon by the surgeon they are at a loss how to manage the patients properly and how to treat post-operative complications should they arise. The hospital clinic has been a veritable *tableau vivant* to them, wherein the sacred mysteries of the dressing-room have not been invaded. Each part is acted with well studied exactness, and the multitudinous details of prearrangement and subsequent care are lost in the admiration of the brilliant performance. This condition of affairs has resulted in a surgical mortality which is considerably higher in cases operated upon outside of hospital walls, and left to the care of an attendant who is unskilled in this department of surgery, than that shown by hospital statistics, and has led an eminent specialist to remark that the surgeon loses his patients more frequently not through any faulty methods at the time of operation but through the incompetency of the attendant who subsequently has charge of the case. Of late years medical schools have endeavored to change this condition by inaugurating a system of ward class teaching, the students being taken to the hospital wards and the progress of recovery from operation studied at the bedside. Although this is a move in the right direction, the necessary infrequency of the visits of the ward classes cannot result in that thorough capability which is demanded of him who has a serious case in charge, and it is only those who are fortunate enough to enjoy the benefits of a hospital training, and who are in constant attendance upon the patients entrusted to their care, with the opportunities to study and carry out the modern principles of after-treatment, who can be considered perfectly competent in this direction. For the benefit of those who have not been so fortunate as to have this training the writer desires to trace briefly the management of operative cases, with the treatment of possible complications, from the time the patient is lifted from the operating table until he may be considered out of danger and the period of convalescence is fully established.

The patient after operation, the wound having been dressed, has his skin surface thoroughly dried with warm towels, and is enveloped in warm woolen blankets and transferred to his room. The selection of the room which the patient is to occupy during the period of recovery from operation is

an important consideration. It should be large, airy, and well lighted. Its dimensions should be such as to allow sufficient air space for two persons—the patient and the nurse. Carpet should be removed from the floor, and after the floor has been thoroughly scrubbed with soap and water and mopped with a disinfectant, a rug is thrown at the bedside, which will add much to the comfort of the nurse. The bareness of the floor is a safeguard against infection, as there is much less danger to the wound than where the atmosphere is constantly filled with dust from a soiled carpet, an efficient carrier of germs. Pasteur was the first to point out that a room full of dust is a source of great danger, as in the air of a room there are held in suspension particles of organic matter, epithelium, exhalations from the lungs, desquamations from the skin, and floating particles derived from clothing and other sources. All these finally settle on the carpet, are again set in motion by the movements of the occupants of the room, and the dust held in suspension may act as a carrier of septic germs and cause infection in the wound. The air in the room should accordingly be frequently changed, and an open fireplace in which even in warm weather a stick or two may occasionally be burned is a desirable feature of the room, as it promotes ventilation; when this feature is not present ventilation should be carried out principally by opening the upper sash of the window. The younger Gross was in the habit of telling his classes yearly a method of ventilation which was unique in its way, and which he invariably carried out when operating in private houses. At regular stated intervals the patient was wrapped in blankets, and the attendant swung the door of the room to and fro rapidly, which changed the air in the entire room in a few minutes' time. Care should be taken to avoid direct drafts, as the local congestion and inflammations which they are liable to produce may seriously interfere with the satisfactory progress of the case. Steam is the most desirable way of heating a room, and the temperature should be kept equable and as near to 70° F. as possible. In operations on the air passages the atmosphere of the room should be kept moist by steam escaping from the discharge valve in the radiator, or by a kettle of water simmering on a gas-stove.

While thorough ventilation and cleanliness are prime requisites for the sick-room after a surgical operation, much can be accomplished

in this line by the disinfection of the room and contents. The floor, the window ledges and other woodwork, as well as the walls and ceiling when these are not covered with paper, are washed with a solution of mercuric chloride (1:1000), or a solution of carbolic acid (1:20), or of chloride of lime (1:100). The latter two have the advantage of being deodorizers as well as potent germicides, and their frequent use as such will be indicated when the discharges from suppurating wounds are very offensive. There should be no open drain in the room on account of the gases emanating therefrom and the great difficulty of keeping it clean, but much trouble is saved if there be a bathtub and water-closet in a room adjoining, the hygienic state of which should be looked after by a skilled person.

The various medicines, solutions, dressings and other utensils of the sick-room should be neatly arranged on a table in a convenient position and screened from the sight of the patient. No dirty dishes or soiled vessels should be allowed to stand about the room.

While an iron bed is always preferable on account of the ease with which it can be kept clean and precautions can be carried out against the invasion of vermin, a wooden bed thoroughly cleansed will answer as well. The patient should lie upon a moderately firm but elastic mattress, preferably made of hair, and a piece of rubber cloth should be placed across the mattress as a protection against involuntary discharges and possible soiling at the time the wound is being dressed. A folded draw-sheet is spread over the rubber cloth, which can be readily removed when soiled and replaced with a clean one, without materially disturbing the patient. A single bed, open on both sides, is more desirable than a wide bed on account of the ease of access to both sides of the patient, so that his wounds may be dressed without unnecessarily disturbing his position. The bed should stand in the room in such a position as to be accessible from all sides, as instantaneous action may be demanded in some conditions, as in sudden secondary hemorrhage, and a bed in a corner might be a source of delay and danger. Should the bed be low, it may be raised by placing a block under each foot, which will facilitate the nurse's care of the patient. The bed-covering should be light and frequently renewed, as patients are often made uncomfortable by too heavy or too warm bedclothing. That amount which

will be most comfortable to the patient will be the best guide. The utmost care should be observed in arranging the sheet on which he lies, removing the folds underneath his back so as to lessen the liability to bed-sores.

*Position.*—The position of the patient in bed is important, and as a general rule that position which will best conduce to his comfort is the proper one. Comfort must always be recognized as a therapeutic measure of some importance, and the careful arrangement of the patient in a restful position is an item in the after-treatment which will assist materially in obtaining a gratifying and satisfactory result, while a disregard of this particular will often strongly militate against a speedy recovery. But in seeking means to make the patient comfortable, the attendant must not be overzealous nor must he annoy the patient by any meddlesome attentions. Answering every whim of the patient, and changing his position every few minutes, will not only weary the attendant, but will destroy confidence in his capability of properly caring for him.

While the patient may be permitted in the main to lie in whatever position is most comfortable to him, and to change this position frequently at the discretion of the attendant, there are certain postures to be maintained, varied in accordance with the operation performed, which have been found best adapted to the successful treatment of different conditions. In operations on the mouth, throat, and upper air passages the head should be lowered to prevent a possible "Schluckpneumonie," and if the operation be on one side of the mouth or throat—as for example the removal of a sarcomatous tonsil—the patient should be turned on the sound side while being fed, as it will facilitate his swallowing without pain. In operations on the head, neck, and chest, elevation of the upper part of the body is preferable, the patient having a pillow placed beneath his back, and several under his shoulders and head, unless some complication should contraindicate this procedure. In operations on the breast the patient lies partially on her sound side, supported in this position with pillows, and the arm of the injured side is anchored closely to the chest-wall with a binder held tightly with shoulder straps, the forearm being flexed across the chest. In operations on the upper extremity the arm will be dressed in a suitable splint, and will be laid in an easy position on a down pillow placed alongside the body.

After operations on the spinal column it

may be necessary to keep the parts operated upon separated by placing the patient in an extension apparatus, the extension being made from the chin and occiput by a padded ring fitting loosely around the neck, counter-extension being maintained by raising the head of the bed so the body will have a tendency to slide downward. The patient may, at the same time, be placed in a wire cuirass, or plaster cast, to immobilize his body, a trap-door being located over the operative area to facilitate proper care of the wound.

After operations on the thorax, as in paracentesis, thoracotomy, or rib section for empyema, the patient will generally rest with more comfort on the intact side, but should occasionally be turned on the side operated upon to favor drainage. When ribs are fractured, after the ordinary dressings are applied confinement to bed is usually made more agreeable by sitting upright, supported by a padded bed-rest.

After operations for appendicitis and other abdominal and pelvic ailments, and in plastic work upon the female perineum, the dorsal position should be maintained for the first twenty-four hours, the thighs being flexed and supported by one or more pillows rolled firmly, so as to relieve the tension on the abdominal parietes. The first day passed, the patient should be carefully turned on her side. This can most easily be accomplished by rolling the patient over, as an assistant draws the draw-sheet partially from under her. This maneuver will not only change the patient's position, but will bring her to a cooler part of the bed. A pillow is placed between her knees, the thighs still being flexed, to promote her comfort. The writer cannot agree with those surgeons who would keep their patients in the dorsal position, week in and week out, after an abdominal section, in the hope of preventing a ventral hernia by this method. The depression to the nervous system which results from this constrained position is far more injurious than the slight risk run by turning the patient on her side, the abdomen being firmly supported by adhesive straps and bandages. It is frequently noticed that patients who are worn out and wakeful by the strain of the first twenty-four hours, will drop off into a quiet sleep when turned over on the side.

In operations for urethral stricture and vesical calculus, a wooden "spider" is placed across the hips of the supine patient, to remove the weight of the bedclothes. To this wooden frame is loosely tied the tube whi-

conducts the urine from catheter or drainage tube to a partially filled jar of antiseptic solution by the bedside, and the patient is cautioned not to move without assistance lest he disturb this appliance.

After operations on the lower extremity splints—extension or plaster of Paris—are brought into use, the leg being usually raised on pillows, or in case of extension with weight and pulley the head of the bed is lowered so as to get counter-extension from the weight of the body, and sand-bags are placed on either side of the limb to hold it steady, the patient lying on his back. In these cases, in order to keep the bedclothes from pressing on the toes and limb, the wooden "spider" is again brought into use.

In some instances it becomes necessary to place the patient in a rather uncomfortable position to meet the requirements of the case, as for example after the partially successful attempt at reduction of an incarcerated hernia under etherization, and supplementary means are taken to accomplish it by the application of ice and the exaggerated Trendelenburg posture, the body being placed at an angle of forty-five degrees. These instances are few, however, and that position of body or limb which is best adapted to its special treatment is generally the most comfortable for the patient.

*Shock.*—If the operation was a prolonged one, and tedious dissections necessitated the handling and manipulation of organs that are intimately connected with the vital functions, the patient on being returned to his bed will often be in a condition bordering on collapse. He will then have a marked pallor and coolness of the skin, blanched lips, dilated pupils which react slowly to light, the heart's action will be weakened, the pulse feeble and rapid, and respiration will be shallow and irregular. The temperature will be subnormal ( $1.5^{\circ}$  to  $5^{\circ}$  F.), the functional activity of all the organs of the body will be retarded, and the patient will lie in a state of apathy. This is the condition known as *shock*. While these symptoms represent the usual manifestations of shock, they may vary from a mere transient depression of the vital functions to an overwhelming collapse from which there is no reaction, the difference in degree depending largely upon whether the operation involved a vital part and whether the irritation to the sensory nervous system was long continued by prolonged manipulation.

In some cases, instead of the usual torpid form of shock there will be a more active set

of symptoms. The patient becomes excited he throws himself around the bed, cries out, shrieks, and acts like a maniac. This train of symptoms is uncommon, however, and when it occurs the condition is very grave.

As above stated, shock depends primarily upon the peripheral irritation of the sensory nerve tract. As a result of this irritation there is a profound impression on the vasomotor system and there follows a diminution or paralysis of the vascular tone, especially of the arteries, and a later dilatation of all the blood-vessels, as illustrated by the well known experiments of Goltz. By the paralysis of the muscular coat of the smaller arteries the blood-current loses part of the force by which it is propelled, the speed of the current lessens, the blood-pressure diminishes, and the blood dams back into the large visceral veins, particularly those of the abdominal organs. In addition to this the right heart, which is only a highly specialized part of the venous system, becomes overloaded and distended, cardiac action is interfered with, the pulse grows weaker, the vital centers are robbed of needed blood-supply, and the functions of life drop below the normal. While the chief factors in the production of this condition are the violent irritation to which the sensory nerves are subjected under the surgeon's knife, the profound impression on the splanchnic system, and the reflex vasomotor paralysis which results therefrom, shock is distinctly increased and deepened by several accessory phenomena, the most important of which are the dissolution of the blood from the anesthetic as pointed out by J. Chalmers DaCosta, the great and rapid reduction of animal heat occasioned by the conditions and environment of the patient on the operating table, and excessive hemorrhage—the increase in the gravity of the condition usually being in direct ratio to the magnitude of these additional evils.

There can be no doubt, also, that mental emotion plays an important part as a predisposing factor in shock, and in all cases is a powerful element in determining the immediate consequence of the operation. Fright before an operation, and the conviction that the ultimate outcome will be fatal, may leave the nervous system so seriously affected that it is unable to recover itself after the operation is completed. The vital centers may even be so depressed as to interdict operation, and in some neurotic subjects only the most urgent indication, as for example a strangulated hernia, will sanction surgical

interference. The celebrated case of Dessault may be mentioned in this connection: he was outlining with his finger-nail the proposed incision for lateral lithotomy, and his patient expired on the table before the knife was used.

Some persons bear operations well, and come out of the anesthetic with no untoward symptoms. To this class of patients belong those who have by reason of their disease been long confined to bed and have become injured to suffering, and those who by a prolonged influence of drugs have acquired a certain torpidity of the nervous forces, that makes them less susceptible to influences which in other individuals would cause a high degree of nervous excitability. Children and the elderly usually rally quickly from operations, the former from the natural recuperative powers of early life, the latter from the dulled nervous susceptibility incident to old age. The accompaniment of marked hemorrhage in operations upon children, and the presence of organic disease in those past middle life, makes each, however, liable to suffer the effects of operation.

Shock in greater or less degree usually follows every operation of gravity, but even in minor operations on certain regions its effects upon the individual are often noticeable, and indeed may be of any grade of intensity, from a slight, evanescent, and barely appreciable disturbance of nerve force to the most pronounced general depression. The effects of the passage of a bougie, the division of the cord in castration, slight operations on the testes, or on the anal and rectal regions, are well known, and the shock resulting is not uncommonly as severe as that following the more extensive abdominal operations or the section of the thigh bone in amputation. The minor details of major operations are also a prolific cause of shock when due caution is not faithfully observed, as, for example, in performing an abdominal section the pinching of the ovaries in their removal will cause a vast amount of shock. Goodell has on a number of occasions noticed the fall of the pulse when these organs were caught by the forceps.

The maximum of shock occurs almost immediately after the operation, and if the case be uncomplicated with hemorrhage or other serious drawback, and if the patient be properly cared for, he will recover from the immediate effects of the operation after the lapse of a few hours. The existence of complications will lengthen the period of reaction according to their severity.

The indications for treatment are to prevent any further loss of body heat, to replace the amount that has been lost by supplying artificial heat, and to combat the vasomotor paralysis. Necessarily it will be understood that prophylaxis before and during the operation is of the utmost importance in combating the subsequent shock, and if due precautions are taken to prohibit any baleful influences on the patient's nervous system beforehand, and to keep him warm and protect him from being drenched with the various solutions while the operation is in progress, and to administer the anesthetic judiciously, the need for urgent subsequent attention will be greatly lessened. During the operation there is often too much exposure of a vital area. In the hurry of the preparation of the patient for the surgeon's knife, especially in emergency cases, the parts surrounding the operative area are at times unnecessarily exposed, and an antiseptic sheet offers but little warmth to the dangling extremities. Very often the body is wet with the fluids from irrigation of pus cavities, as in an abdominal section for suppurative peritonitis, the proper precautions for draining the fluids from the table not having been taken; or the patient may be soaked in perspiration. Added to this, the enormous abstraction of body heat incident to the evaporation of ether throughout the large mucous membrane surface of the lungs, and the coincident alteration in the blood composition, and we have conditions that favor a signal collapse of vital forces.

To supply warmth, then, is the first consideration. By enveloping the patient in some warm non-conducting fabric—the best of all being a woollen blanket—and surrounding him with hot-water bottles or bags, or hot bricks, we not only prevent any additional loss of heat by radiation, but overcome the previous loss. These bottles, safely corked, are placed external to the blanket covering the patient and located about him in such a way as to avoid the possibility of burning him—*i.e.*, they are placed *around* him, and not *against* him. The nurse in charge should frequently inspect them to see that they do not become misplaced by the restive movements of the patient coming out of the anesthesia. Undue proximity of these hot-water bottles has resulted in deep and painful burns, the patient's thermal sense being obtunded by the anesthetic, much discomfort has been caused, and convalescence has been prolonged for weeks. The writer has in mind a case wher

the temperature dropped so low after operation as to cause some alarm, and the careless placing of hot-water bags produced an angry ulcer reaching from the loin to the calf of the leg, which kept the patient bedfast three weeks after the operation wound had healed; and it was only after convincing him later of the necessity of urgent counter-irritation that a legal suit was avoided. The hot-water bottles may be supplemented by a portable hot-air apparatus consisting of an alcohol lamp and a tin tube which conveys the heated air under the bedclothing. It will be necessary to change the position of this apparatus every few minutes, as the current of air that is established is so heated as soon to become unbearable for any length of time near a single part of the body.

The beneficial effects of the application of external heat will be augmented in large degree by the administration of hot stimulant enemata, six ounces of hot, strong, black coffee being introduced high up into the colon, through a large-sized catheter or rectal tube. This will not only give additional warmth to the body, but will by its reflex action stimulate the flow of blood in the distended abdominal vessels. The head of the bed is lowered to favor the flow of blood to the anemic vital centers in the brain and medulla, and a nurse assists materially in promoting this flow towards the devascularized areas, and in emptying the abdominal vessels, by practising light local massage to the abdomen, effleurage (stroking) and petrisage (kneading) with both hands for ten or fifteen minutes, after which a compress of rather large size is laid over the abdomen and pressure exerted with a circular binder so as to prevent the vessels from again becoming distended. With a view to limiting the amount of work required of the heart, by diminishing the area over which the blood in the body has to be distributed, in serious cases it is well to raise the limbs, surround them with warm cotton-wool, and bandage them rather tightly, beginning at the distal end. This method of bandaging the extremities is considered superior to the plan suggested by an eminent surgeon, of using an Esmarch bandage. The circulation is sufficiently controlled by raising the limbs and the moderately tight application of the cotton bandages, which are always at hand and in sufficient number, and there is the additional advantage of the heat conveyed and sustained by the warm cotton-wool.

Sinapisms (mustard plasters) should be

placed over the cardiac area to stimulate the flow of blood toward the heart and strengthen its beat.

The employment of hypodermoclysis and saline transfusion in the treatment has led to some discussion among surgeons as to the efficacy of these measures in certain forms of shock, particularly in those cases uncomplicated by hemorrhage at the time of operation; and in considering the question whether saline solution should be introduced into the circulation in every severe case, various theories have been set forth to show why only those cases in which considerable blood has been lost will be benefited by these measures, and that in those cases uncomplicated by hemorrhage little or no good is accomplished by the transfusion of fluids. Such, however, has not been the result gained from hospital experience. In cases where profound shock has followed upon minor and bloodless operations, as well as upon operations of gravity, the vascular tone and blood-pressure have been quickly reestablished by the injection of eight ounces to a pint of Thiersch's solution into the circulation. In this connection we may note a recent case in the service of Dr. J. Chalmers Da Costa, in the Jefferson Hospital, where a violent kick in the abdomen, sufficient to lacerate the bowel in two places, left the patient in such deep shock and with such a weak pulse that it was feared operation could not be performed. The intravenous injection of a pint of warm saline solution had a most happy effect, the pulse becoming full and more regular, the temperature rising in corresponding degree. Numerous instances could be cited, both from the writer's experience and in observing that of others, where similar effects have been noticed after hypodermoclysis and intravenous injection in shock following operations, during which the amount of blood lost was so small as not to be estimated.

While the employment of these measures is not advised as a routine treatment in all cases of shock—those of less severity responding to the treatment set forth above—there can no longer be any doubt, from the observations in a large surgical clinic, of the efficacy of these methods in severe cases, whether the condition be one following operation in which an enormous quantity of blood was lost, or whether it be due solely to the profound impression of a bloodless operation.

This fact is not without scientific reason. When it is remembered that in shock the

vasomotor system is paralyzed, and that the blood-vessels of the body are greatly relaxed, and that the blood, although still existing in normal amount, is stagnant in the large relaxed vessels of the internal viscera, it becomes evident that the depression and failure of the vital functions result not from the abstraction of a large quantity of blood from the *body*, but from the damming back of the still existing normal quantity into the widely dilated abdominal vessels. The vital centers, principally those in the brain and medulla, are left without the needed blood-supply to carry on the functions of life in a normal manner. The patient has practically bled into his own vessels. It will accordingly be seen that hypodermoclysis or saline transfusion perform here the same office they do in cases in which a large quantity of blood has been lost during operation. In both instances the vital parts of the body have been depleted, and in both the saline solution has a like effect, supplying to temporarily empty vessels a physiological substitute to contract upon, and affording anemic centers opportunity to be replenished and to functionate.

In severe cases it is advisable to institute these measures at once to bring about reaction, in conjunction with, and not depending alone upon, the simpler means used in the treatment of less marked conditions. As a means to this end we have recourse to several different methods. Transfusion of blood, both by direct and indirect method, is an old procedure that falls short of what was anticipated for it, and is but little used at the present day. Its theoretical usefulness has been disproved by the discovery of Panus, who showed conclusively that defibrinated blood is just as efficient as pure blood for overcoming the effects of hemorrhage, and this paved the way for the modern use of salt solutions, as it indicated that the saline elements are those which are required; and since transfusion of blood has largely been superseded by hypodermoclysis and the intravenous injection of saline solution, clinical experience has proved that the latter methods are even more efficacious in supplying volume and restoring a rapidly failing circulation than is human blood. Another point in favor of salines is that they can readily be obtained and used with much more ease. Of their value in combating shock when not a moment of time is to be lost there can no longer be any question.

During the term of service of the writer as hospital interne there were two particularly

alarming cases of shock following operations in which considerable blood was lost, where instant action was demanded to revive the patients. Both cases were amputations at the upper third of the thigh—one in the service of Professor Brinton, the other in the service of Professor Hearn—and in each case the condition was exceedingly grave, and the patients were undoubtedly saved through the timely employment of saline transfusion.

When should hypodermoclysis be performed, and when saline transfusion? When the case is not so urgent, and when one can act with deliberation, perform hypodermoclysis. When the symptoms are alarming and life is about to ebb, and when seconds must be considered minutes, perform saline transfusion.

The simplest method for performing hypodermoclysis is to fill an ordinary rubber fountain syringe that has been thoroughly cleansed with normal salt solution (0.60 per cent.) made by adding a drachm of table-salt to one pint of boiled water. The water must be sterilized by boiling, and at a temperature of 101° F. when poured into the syringe—it will lose a degree in passing through the tube. At the end of the tube is attached a small-sized aspirating needle, also sterilized by boiling, which is plunged beneath the skin into the subcutaneous cellular tissue of the pectoral region, flanks, thighs, or between the scapulæ. The syringe is raised a distance of half a meter above the surface of the body, and the solution must be running through the aspirating needle while the needle is being inserted, so as to prevent the unnecessary introduction of air beneath the skin. About half a pint is allowed to flow in one place, when the needle is withdrawn and inserted at another site, until several pints have passed into the cellular tissue, which will require a half hour or more to accomplish. The swellings produced by this procedure are rubbed and kneaded until absorption has taken place, which requires about twenty minutes. The point of the needle puncture is sealed with iodoform colloid to prevent infection.

A convenient apparatus for intravenous saline transfusion consists of a cannula, rubber tubing half a meter long, and a funnel. The median basilic vein is exposed, and two catgut ligatures half an inch apart are placed under it. The distal ligature is tied and the vein nicked between the ligatures. The cannula is now inserted into the opening in the vein, and is held in position by tying the proximal ligature. The cannula is filled

with saline solution and is then connected with the tube and funnel, which are also filled with the solution at once to displace the air. The funnel is raised above the part and the saline solution enters the vein. The funnel should be kept well filled by adding more solution as the fluid continues to run into the vein, so as to prevent air emboli from entering the circulation.

The amount to inject depends upon the effects on the patient's pulse, which are noticeable after several ounces of the solution enters the circulation—usually from half a pint to a pint will suffice. In emergency an ordinary glass syringe will answer the purpose of the funnel and cannula. Professor Keen uses the apparatus of Collin, which renders the entrance of air impossible.

These methods of introducing saline solution into the circulation have undoubtedly helped to reduce the mortality of major operations in recent years.

While these measures are being carried out, we dare not neglect the therapeutics of shock in a different manner. In the selection of the proper drugs to administer we are met with the contentions of a number of observers, but in the writer's experience no drugs have acted so well as ammonia, alcohol, and atropine, mentioned in the order of their administration. They are given in very small doses, and at short intervals, until the pulse improves, the skin assumes its accustomed glow, the temperature rises, and the brain becomes more active.

As shock finds its expression in a vasomotor paralysis, the therapeutic indications are to counteract the effects of this condition.

The patient is apathetic and often nauseated after the anesthetic, and is unable to engage in the effort of swallowing solutions which would make the stomach more rebellious, so the administration of medicines by the mouth is out of the question. As the immediate effect of the drugs is desired, the medicines are most advantageously given by subcutaneous injection. If the case be extremely serious and prompt intervention is demanded, the drugs should be injected directly into a vein, preferably at the bend of the elbow, as the veins in this region are large and superficial and easy of access. The median basilic is usually selected for this purpose. The ammonia and alcohol are preferably administered together, as each of them being a diffusible drug and having its own special action on the circulation, one reinforces the other, and hastens the effects on

the system. The combination exists in the spiritus ammoniæ aromaticus, which is administered hypodermically in half-drachm doses every fifteen minutes until its effects are noticeable. The ammonia will act quickly and cause a rise in the arterial pressure, due to its action upon the peripheral vasomotor nerve fibers, and upon the muscular fibers in the coats of the arteries. The alcohol will be a direct stimulant to the rate as well as to the force of the heart's beat—so that there will be a direct action on the circulatory tract where it is failing. As the effects of both the ammonia and alcohol are fugacious, and their virtue lies almost solely in the rapidity of their action, it will be necessary to reinforce them with hypodermics or a more decided and more permanent vasomotor stimulant, namely, atropine sulphate, which is also given hypodermically from the start in doses never greater than  $\frac{1}{160}$  grain, and repeated at half-hour intervals until the patient has reacted from shock. Large doses at more frequent intervals have a tendency to invite a subsequent depression. The atropine produces a rise of arterial pressure by stimulating the vasomotor center, and is the most powerful vasomotor stimulant at our command, as proved by the experiments of Hare, and corroborated by clinical experience.

The vaunted administration of digitalis, calabar extract, nitroglycerin, and possibly strychnine, from which much was expected in the treatment of shock, have all proved fallacious.

To sum up, therefore, the treatment of shock following operation:

1. Prophylaxis before and during the operation.
2. Wrap the patient in a warm blanket and apply hot-water bottles or hot bricks, and a hot-air apparatus.
3. Lower the head and shoulders.
4. Apply sinapisms to the precordium.
5. If severe shock, perform hypodermoclysis; if alarming, perform saline transfusion.
6. Give an enema of six ounces of strong, hot coffee.
7. Massage the abdomen and apply an abdominal compress.
8. Elevate the limbs, surround them with cotton-wool, and bandage.
9. Administer hypodermic injections of liquor ammoniæ aromaticus in half-drachm doses every fifteen minutes, and atropine sulphate  $\frac{1}{160}$  grain every half hour, until reaction sets in.

[To be continued.]

THE EXACT TREATMENT OF MALARIAL  
FEVERS.

BY CHARLES D. SLAGLE, M.D.,  
Portsmouth, Ohio.

In the treatment of malarial fever a two-fold object must constantly be kept in mind: first, the treatment of the disease in question; and second, to prevent further infection. By what mode the *plasmodium malariae* gains entrance to the system is at present unknown. It is thought, however, that infection is more liable to occur at night. The disease shows no preference to either sex and attacks all ages. In the treatment of regular forms of intermittent and remittent malarial fevers of whatsoever type, it is the duty of the physician never to allow the recurrence of a paroxysm after once the diagnosis has been made. Injury may be done to the blood. The treatment of malarial fevers in general may be divided into that for the cold, hot, and sweating stages, and for the permanent cure of the disease.

During the cold stage the patient should either be put to bed and wrapped well in woolen blankets, and hot-water bottles put to his limbs and body, or should remain in a very warm room having a temperature from 85° to 90° F. A ten-grain dose of Dover's powder should be given early in this stage. Stimulants may be given if this stage be severe, but one objection arises to their use, on account of their causing severe headaches. They should be given in amount to affect the vasomotor system only. None is better than the old French brandy. The cold bath has been recommended during the cold stage. This was practised as early as 1835, and good results seem to have followed its use. Some physicians employ hypodermically, at the close of this stage, pilocarpine in pretty good doses, and it is said that it cuts the hot stage shorter. Its use should be guarded.

As to the hot stage: Do not give quinine at the beginning of this stage; it may cause delirium. The patient should be made as comfortable as possible. He should be placed in a well lighted and ventilated room and cool refreshing drinks be given. The ice-bag or cloths wrung out of ice-water may be applied to the head. The body may be sponged with cold or tepid water, or even the cold bath be given, which affords great relief. A diaphoretic may be given, such as Dover's powder or pilocarpine. Preparations should be made for the oncoming sweating stage: When this stage arrives the

patient should, if not before, be placed in bed and hot drinks, such as hot lemonade or a hot whiskey toddy, be given to promote a free flow of perspiration. Other treatment is not really needed, except the change of the clothing and sponging of the body after this stage has subsided, taking care to avoid any undue exposure to cold.

When the diagnosis of malarial fever has been made, what is the exact treatment which the physician should pursue? The first thing to be thought of is to prevent the next paroxysm. If you have not treated the patient through the various stages of the first paroxysm—and in a large proportion of cases the physician is not called until a few hours after the first paroxysm, or possibly he may be called during the sweating stage—you learn from the history of the case the nature of the trouble and at once institute your treatment. In quinine there is a specific in the treatment of malarial fevers. Of the very few drugs in the physician's armamentarium which are called specifics, quinine in my estimation should rank first. It is the one specific which may be relied upon and good results expected to follow its use. As soon as the paroxysm is at an end commence its use. It was formerly believed that the administration of quinine in large doses (twenty-five to forty grains) was productive of the very best results, but later research has revealed two objections to this radical treatment: First, the poisonous effects that may be produced and even profound fatal cinchonism that may prevail, some patients being very susceptible to its effects; second, it is not necessary to give such large doses of quinine. We can reduce the temperature without such treatment. The sole influence of the quinine is to cause the death of the *plasmodium malariae* or germ producing the malarial fever; the object being to saturate the blood and by such means kill the little germ, arresting the next paroxysm. The ordinary rule is to administer the quinine in small and frequently repeated doses—two to three or four grains every hour or two—so that by the time for the next paroxysm the patient may have taken from half to one drachm. It should be continued until the effects of cinchonism are produced. This is ascertained by the tinnitus aurium which the patient experiences.

If the type of malarial fever be the quotidian intermittent, the chances that the paroxysm will or will not return again are about even. If of the tertian or quartan type, it

may safely be said that the paroxysm will not return. Cinchonism is a sign that the system is fully under the influence of the quinine and that the *plasmodium malariae* has been destroyed, although in a few hours, if of the quotidian type, the patient may have a paroxysm. This can only be explained by the fact that a new set of hematozoa have reached a certain period of development before the effect of the quinine was fully exerted upon their growth. Give preferably the sulphate of quinine in divided doses and during the intermission of the paroxysm. It is best administered in solution. One drop of the aromatic sulphuric acid to the grain of quinine makes a very good pill mass. Three drops dissolves it readily, to which water may be added to form a solution. The same is true of tartaric, lactic, citric and nitric acids. If the taste is too intensely bitter for the patient a syrup may be used, as that of licorice or yerba santa. A favorite prescription is the following:

R Quinine sulphate, 1½ drachms;  
Syrup yerba santa, 4 fluidounces.

M. Sig.: One teaspoonful every two to three or four hours for an adult. The bottle should be shaken well before using.

If still too bitter give in capsule or konseal form. Sometimes fruits or candies may be used to destroy the taste. To children the preferable mode is to employ the quinine in a syrup, as in the above prescription, in doses proportionate to age. The following serves well and should be tried:

R Tincture iron chloride, 2 fluidrachms;  
Quinine sulphate, ½ ounce;  
Tincture chinoidine, 6 fluidrachms;  
Distilled water, 1 fluidrachm.

M. Sig.: Ten to twenty drops for an adult should be taken in some water every three or four hours.

The effects of cinchonism may be reduced by combining caffeine citrate (half a grain) with quinine (two grains). Antipyrin, antifebrin, and phenacetin in three- to five- or six-grain doses also reduce the effects of quinine upon the system. These remedies have a tendency to relieve muscular pain, headache, etc. Their effects should be carefully watched. Opium in some form, as Dover's powder, may also be used. To reduce the temperature aconite may be used *per se*, or it may be combined with an opiate, as the tincture of Dover's powder. Some of the above mentioned coal-tar derivatives may also be used. The fluid extract of pilocarpine or jaborandi may be used to advantage in doses of five to ten drops. Aromatic sulphuric acid in four- or

five-drop doses in water every two hours acts well as an antipyretic. A warm bath may be given. If the paroxysms be postponed it is good evidence that results are being produced. If the patient grows worse it shows that quinine is not being used, or that it is adulterated, or that a complication has set in. When the paroxysms have been stayed a purgative may be given as follows:

R Calomel, 3 grains;  
Sodium bicarbonate, 12 grains;  
Sugar of milk, 12 grains;

M. Make into 12 powders. Sig.: One powder every hour until bowels move freely.

Jalap in small doses may be combined with the calomel. Salicin may be given in fifteen-grain to one-drachm doses until effects are produced, and repeat *pro re nata*. A saline may also be employed.

Large doses of purgatives and emetics were formerly used in the beginning of the disease, from the belief that the gastro-intestinal tract should be cleansed before commencing the antimalarial treatment. Nowadays we first begin with the antipyretic treatment and defer the purges until later. Bleeding was at one time thought to be productive of very good results, but such treatment is no longer considered.

Occasionally a patient is found who has an idiosyncrasy to quinine. In such cases what is to be done? The cinchonidia sulphate in doses twice the size of those of quinine, or the cinchona sulphate in doses about three times the size, may be given. If the idiosyncrasy be still too great something else must be given. Arsenic in the form of Fowler's solution, in doses of five to ten drops, well diluted, three times a day, is very good. It should be commenced as soon as possible after an attack, and continued. It is impossible to bring the system under the full effects of the arsenic soon; hence it should be continued for some length of time. *Eupatorium perfoliatum* (thoroughwort, boneset) may be used as a substitute for quinine in such cases on account of the intensely bitter principle it contains. This is "the poor man's quinine." Administer it preferably in the form of the fresh fluid extract, in doses of a half to one fluidrachm. It is a good expectorant, cathartic, and emetic, a high diaphoretic, and very good antiperiodic. The sulphate berberine in fifteen- to thirty-grain doses during the apyrexial period seems to yield good results. It does not produce the bad effects that the cinchona salts do. Ferrocyanide of iron (Prussian blue) was formerly

thought to be good; it is probably inert. Chloride of ammonia in half- to one-drachm doses acts very well during the intermissions. Nitric acid in three- to eight-drop doses, well diluted, may be given every four to six hours. Strychnine in  $\frac{1}{100}$ - to  $\frac{1}{50}$ -grain doses may be used. Potassium iodide was formerly thought to be curative, but it is doubtful if it has any effect upon the plasmodium. Piperine with cinchona may be used. In all cases the cardiac action should be closely watched.

Oftentimes a patient is found whose stomach is so irritable that it will not tolerate the quinine. In such cases use the quinine or antiperiodic enema per rectum in twice the size doses as per os. Only use hypodermic injections of quinine in the more malignant types of the malarial fevers.

What shall be done during the period of convalescence to prevent the recurrence of another attack, and to prevent further infection? It is not correct nor is justice done to the patient to interrupt the treatment at once. Keep the patient under the influence of the remedy until the plasmodium has been entirely abolished. This may be ascertained by a microscopical examination of the blood. If none be found, and after a few weeks' continuous treatment, it may be safely said that the patient is free of malaria, although some cachexia may remain. A tonic should always be given. Prescribe iron and gentian or *Cornus florida* (dogwood). Of the latter give the fresh fluid extract of the bark. The phospho-muriate of quinine is a good tonic. It contains iron, quinine, strychnine, and the phosphates in a pleasant vehicle. Strychnine in appropriate doses is often prescribed. The tonic should be continued for some time after convalescence has been established. The above line of treatment answers very well in the ordinary or regular intermittent and remittent forms of malarial fevers. The dose of the antiperiodic should be larger in that of remittent fever.

To prevent further infection in a malarious district, it is well for the patient to continue the quinine in one- or two-grain doses three times a day, or its succedaneum in proportionate doses, for a considerable length of time. The patient should be removed, if possible, from the infected district until the malarial taint has been entirely eradicated from his system. Send him to a community where malarial fevers are unknown.

A few words in regard to the diet for a patient suffering with malarial fever. Only those articles of food which are completely

dissolved in the stomach and those which leave little residue should be given. Milk contains all the elements of nutrition in a concentrated form. One may live on a milk diet for a considerable length of time. If the patient dislikes milk, give something else. Liquid food is one which is produced by artificial means and subserves the use of solid foods. It should be given to a patient in a condition to convey the greatest amount of nutritive material in the smallest bulk. It should be as near a solution as possible. Beef-juice and broths, eggs poached or lightly boiled, soups, jellies, toasted bread, with cream and sugar; oatmeal in large quantities acts as a laxative; rolled oats, rice well cooked, and some fruits. Beef-tea is a very good stimulant, but possesses next to nothing in point of nourishment. Dr. Thudicum, of Liverpool, England, said a few years ago that beef-tea contained the elements of urine. This is no doubt true to a great extent, but nevertheless many physicians daily prescribe it as one of the principal constituents of the menu of the sick-room.

The irregular forms of intermittent and remittent malarial fevers are more intractable and do not yield so readily to treatment. The pernicious type is fortunately very rare in temperate climates, but is frequently seen in the south and tropical countries. There are several forms of this pernicious type, chief of which are the algid, gastro-intestinal, comatose, delirious, and hemorrhagic. Two types may combine to form a new one. The treatment of all the types should be symptomatic during the paroxysm and through the intermission, to prevent the next one. The quinine should be administered hypodermically in pretty free doses, care being taken not to cause an abscess. It is best to administer the muriate of quinine and urea in solution. This form of quinine and the urea seems to act more forcibly. A sufficient amount should be given to induce cinchonism as soon as possible. After the paroxysms have been stayed, then follow the course of treatment outlined above.

The gastro-intestinal type is sometimes mistaken for cholera morbus. The disease soon yields to antiperiodic treatment.

A word in regard to the treatment of the hemorrhagic type. It is in this form that we observe the malarial hematuria. This form is always found in malarial districts, and if the malarial fevers be treated properly a less number of these cases will be observed. A

thors seem to differ in the treatment of this form. Quinine hypodermically, in five-grain doses every three hours, should be given to act early on the development of the parasites.

Malarial hematuria or hemoglobinuria is due to a peculiar form of the parasite of Laveran, and if our line of reasoning be kept up, quinine should form an important part of the treatment. The patient should be placed in bed, kept warm, secretions opened freely, and the kidneys spared. Gallic acid in five- to ten-grain doses every two to four hours may be given. Tincture laricis cortex in twenty- to thirty-minim doses every three to four hours serves well. In this form there is a great tendency to heart failure. The cardiac stimulation and tonics with good food should be kept up.

The mortality from any of the types of pernicious malarial fever is high, and if the treatment be not active from the outset, little or no results may be expected.

The æstivo-autumnal or typho-malarial type, in which the paroxysms are little or not at all marked, and the fever more or less continuous for several weeks, appearing late in the summer or early autumn, usually yields readily to the antiperiodic treatment. After the paroxysms have been broken and some little pyrexia continues, the ordinary treatment for typhoid or other fevers should be carried out.

The more irregular forms of malarial fevers, as diarrhea, brow or sun pain, or anesthesia of arm, neuralgia, especially of fifth, seventh, and sciatic nerves, and menorrhagia in women, are the most frequent. Look for the causes and remove them. The patient should be placed on larger doses of quinine than for a common attack, and in the course of a few weeks good results will be noted.

Dyspepsia may occur in paroxysmal attacks. Use quinine in good doses or Fowler's solution in five- to ten-minim doses, well diluted, three times a day until its effects are noted; it usually effects a cure.

A pneumonia may complicate a malarial infection. Eliminate the malarial element with the antiperiodic treatment, and in thirty-six hours obtain the *crepitus redux*.

Fractures should be watched in a malarious district lest union be slow. Better give a little quinine on general principles. In all, the exact treatment of malarial fevers consists in eliminating the plasmodium of Laveran from the system of the patient by whatever mode and means are best suited to the patient. Tonics and supporting treatment should follow in the wake.

## A CASE OF HYOSCINE INTOXICATION.

BY AUGUSTUS A. ESHNER, M.D.,  
Professor of Clinical Medicine in the Philadelphia Polyclinic;  
Physician to the Philadelphia Hospital; etc.

Hyoscine is in many respects such a useful drug and one so extensively employed that any untoward effects resulting from its medicinal employment seem deserving of record. I wish in this connection to relate briefly the case of a man, fifty-five years old, for many years a sufferer from asthma, who received at 10 P.M. by hypodermic injection for the relief of a paroxysm:

Morphine sulphate,  $\frac{1}{4}$  grain;  
Strychnine sulphate, 1-60 grain;  
Hyoscine hydrobromate, 1-100 grain.

In a few minutes a small measure of relief from the asthmatic difficulty and distress was experienced, but in a few more minutes there was noted extreme muscular weakness, which quickly progressed to a state of general relaxation, with loss of consciousness. The face was markedly flushed and the vessels extremely prominent. The action of the heart was excited, although the rhythm was not disturbed, and no adventitious sounds were audible. The pulse was hard, tense, and full, and the beat about 120 to the minute. The respirations were noisy and labored, and about 40 to the minute. The pupils were of ordinary size. The patient could not lie recumbent, and attempts to get him into bed were desisted from in consequence of the resulting apparent discomfort. There was occasionally slight twitching of the hands, and the knee-jerks were irritable and perhaps a little increased. The patient could be aroused to partial consciousness, but he was not able to speak. At times he made certain incoordinate movements and gestures apparently indicative of his distress and his wishes. He could not be induced to swallow, and his teeth were found clenched when an effort was made to introduce bits of ice into the mouth. The skin was moist and cool and free perspiration followed.

As the patient had on former occasions received without ill results as much as one-fourth of a grain of morphine sulphate hypodermically, and as the symptoms were unlike those of strychnine poisoning (the dose of strychnine being a small, even medicinal, one) and corresponded with those to be expected from hyoscine intoxication, a further dose of one-eighth of a grain of morphine sulphate was injected beneath the skin, and a third dose several hours later. In addition

amyl nitrite was administered by inhalation. The conditions gradually improved, consciousness and power of speech and motor capability slowly returning.

At seven o'clock in the morning, nine hours after the injection, the patient was unable to recall anything that had taken place during the night, and expressed himself as having passed through a comfortable period. He was yet unsteady upon his feet and was unable to pass more than a drachm or two of urine. A specimen from a larger quantity passed during the subsequent day had a specific gravity of 1024 and, although failing to respond to the heat and contact (nitric acid) tests for albumen, contained numerous hyaline and granular casts. Albumen and casts had also been found previously. The patient had on former occasions taken by the mouth without unpleasant manifestations as much as  $\frac{1}{16}$  grain of hyoscine thrice in the course of a night. The pronounced symptoms that thus developed from the hypodermic employment of so small a dose as  $\frac{1}{16}$  grain of hyoscine hydrobromate must be attributed to idiosyncrasy, the undue susceptibility being perhaps intensified by the somewhat debilitated condition of the patient at the time. Of course it is possible that the tablet used contained more than the quantity named, but this is highly improbable.

Untoward results have been reported from the hypodermic employment of even a smaller dose of hyoscine. Thus O'Hara (*THERAPEUTIC GAZETTE*, vol. ii, 26; cited by Wood: *Therapeutics*, 7th Ed., 1888, p. 237) relates a case in which the administration of  $\frac{1}{16}$  grain hypodermically was followed by severe disturbance, lasting for twenty-eight hours, with total lack of remembrance of occurrences that took place during the seven hours succeeding the injection. Root (*THERAPEUTIC GAZETTE*, vol. ii; cited by Wood, *loc. cit.*) records a case in which  $\frac{1}{32}$  grain administered by the mouth gave rise to symptoms of violent poisoning, and even  $\frac{1}{16}$  grain occasioned very pronounced manifestations. Gnauck (*Medical News*, xl, 323; cited in the National Dispensatory, 5th Ed., 1894, p. 855) states that even a very minute dose ( $\frac{1}{32}$  grain) of hyoscine is capable of producing its characteristic effects and, subcutaneously, of acting twice as powerfully as by the mouth. On the other hand, Hutchinson (*Alienist and Neurologist*, iii, 539; cited by Wood, *loc. cit.*) reports that the ingestion of one-quarter grain of very impure hyoscine was followed by quiet coma, with entire muscular relaxa-

tion lasting eleven hours. Further, according to Wood, no case of fatal poisoning is on record.

In explanation of the widely diverse results obtained from the use of hyoscine it must be concluded that different preparations of the drug vary greatly in activity; while some significance is to be attached also to the matter of idiosyncrasy. The best antidote for hyoscine is said to be chloral (National Dispensatory, p. 587); Hare (*Therapeutics*, 5th Ed., 1895, p. 209) recommends pilocarpine.

---

#### THE DUTY OF THE PHYSICIAN TO THE DYING.

---

BY A. L. BENEDICT, M.D.,  
Buffalo.

---

It is no easy matter to define what is meant by the word "dying." In the broadest sense, every one is constantly approaching death or is even in immediate proximity to it, unaware of its presence, and thus may be said to be "dying." But in ordinary, non-theological parlance, the word may mean either that a person is fatally sick or injured, or that he is *in articulo mortis*, and thus within a few hours or minutes of death.

The physician is frequently implored to relieve suffering by means indirectly prejudicial to continuance of life, or even to hasten death; or, on the other hand, the feelings of the patient or his relatives, or the conscientious scruples of the physician himself, may urge the prolongation of life to the fullest extent, regardless of other considerations.

For the production of euthanasia there is practically only one satisfactory drug—morphine. Whether the pain is the acute agony of fatal traumatism or serous inflammation, the ungratified and ungratifiable need of oxygen, or the intense discomfort of utter fatigue, mild hypnotics, the coal-tar analgesics, and similar drugs usually fail utterly. Sometimes inhalations of chloroform are indicated, though the danger of sudden death must always be considered. Occasionally, when the pain is of a spasmodic nature, nitrite of amyl is moderately efficient. Usually, euthanasia and hebetude are synonymous. Occasionally patients are "conscious to the last" without suffering and with the retention of full mental powers. Rarely death is preceded by a period of exaltation, and such cases are carefully treasured by those ser-

mentally inclined, especially when the exaltation is of a religious nature. Fortunately the death-bed scenes of pulpit oratory are almost never witnessed, most persons leaving this world in a dignified and quiet manner. The theoretical objection to using a depressing drug when death is imminent does not, in our opinion, outweigh the claim of the sufferer for peace. We may well urge the patient to endure pain if his sickness is of a transient nature and if the opiate may throw the balance against recovery. But when the end is inevitable, when the alternative is only between, let us say, three hours of comfortable existence and three hours and a quarter of misery, there seems to be no ethical objection to erring on the side of mercy. With regard to the use of morphine or opium in Galenical form, we may well be skeptical as to the possibility of cardiac depression. Indeed, many still hold to its therapeutic value as a cardiac stimulant. In respiratory failure, however, there is real danger of depression of the medullary center.

It is stretching both the term "euthanasia" and the ethical consideration involved to lull the fatally sick into a lethargy days or weeks before death. Morphine cannot be relied upon too long, and if used on too slight provocation there is apt to follow a period in which the dying patient suffers the discomfort of disease plus the misery of the morphine habit. This should always be remembered in the treatment of cancer, and the usefulness of local anesthetics and of milder central depressants should be exhausted before recourse is had to opiates. It is the habit of some practitioners to use opiate cough mixtures freely, especially in consumption. In this connection we need not consider the impropriety of using opium in curable coughs. It is our purpose merely to emphasize the fact that we have no more right to reduce a consumptive to a vegetative existence for several weeks or months prior to death than we have actually to deprive him of organic life. Nor can such practise be excused by the plea that the morphine treatment keeps the consumptive comfortable and stills his complaints.

In medical practise one not infrequently meets emergencies when the humane physician is strongly tempted to break the commandment, "Thou shalt not kill." The misery and disgrace which the birth of a child will entail on a too trusting but really innocent girl, the suffering which we would not be so cruel as to allow an animal to

endure, often appeal most speciously to the heart of a humane man. Yet most of us have religion enough to force the admission that, whatever the circumstances, the deliberate taking of human life belongs to a higher power than the individual human creature. Therefore the only safeguard against the temptation to kill in the cause of mercy is the resolution never to consider the merits of such cases, but to answer their appeals with a firm refusal.

On the other hand there is, in our opinion, no ethical consideration which demands the use of artificial means to prolong the death agony simply for the sake of postponing death. Such treatment would be as strictly an interference with the natural workings of Providence as the cutting short of life. Thus, the hypodermic use of strychnine, nitroglycerin, etc., at the termination of an inevitably fatal sickness, is uncalled for, unless the making of a will, the meeting with a summoned friend, or some similar exigency, calls for the temporary prolongation of life.

On the other hand, in all but the most clearly understood cases the benefit of the doubt should always be given to the patient, and every means should be employed to tide over the crisis. This is true even to the extent of using restorative measures to the apparently dead. The stimulant should first be injected, and then there is leisure to determine whether life has or has not departed. Drowning, mutilating injuries, advanced heart disease, profound shock, apparently fatal syncope from any cause, are instances in which occasional cases may surprise the shrewdest by recovering in the face of an absolute prognosis, or even diagnosis, of death.

#### CALOMEL INJECTIONS IN SYPHILIS.

ASSELBERGS (*Presse Médicale Belge*, November, 1896) uses calomel injections in the following conditions: (1) Certain cutaneous and mucous syphilides, erosion of the tongue, onychia, palmar and plantar psoriasis; (2) ulcerations in general, especially of the tongue; (3) visceral and cerebral syphilis; (4) cases which resist other forms of treatment; (5) cases of dyspepsia in which the stomach will not tolerate mercury by the mouth.

The author does not agree with Julien in advocating it as a routine treatment for all cases, owing to the considerable amount of pain caused after the injections.—*British Medical Journal*, June 26, 1897.

# The Therapeutic Gazette

EDITED BY

### THE THERAPEUTIC USES OF SUPRARENAL GLAND.

The three glands in the body which have so far positively proved their therapeutic efficiency in the treatment of disease produced by or originating in failure of their function are the thyroid, the pancreas, and the suprarenal bodies. Of these the thyroid, as obtained from the sheep, has proved itself by far the most efficacious. Our knowledge concerning the therapeutic efficiency of the pancreas and the suprarenal gland is as yet more uncertain, although of course the therapeutic value of the digestive ferments derived from the pancreas has been decided upon favorably beyond all doubt.

From the physiological action possessed by suprarenal glands, or their extract, it is evident that a greater possibility exists for the production of good results in their employment than their limited administration in the presence of Addison's disease, for the studies of Schafer and others have proved that the adrenals contain an active principle which directly or indirectly powerfully stimu-

lates the vaso-motor system with the result that greater increase in arterial pressure ensues upon the administration of this gland. The recommendation made by Oliver that adrenals be employed in asthenia and anemia seems based upon the lines of rational therapeutics, and the further suggestion that these glands be employed in those cases of diabetes which are perhaps dependent upon dilatation of the hepatic blood-vessels also seems reasonable. The daily dosage of the gland itself, or of its equivalent, should amount to about 45 grains, and it seems evident that they can be given continuously for long periods of time without injurious effect.

There are so many instances met with by the physicians in which the chief ailment of the patient seems to be a functional atony of the vascular and nervous system that we would suggest the wider employment of adrenal extract in such cases. In earlier issues of the GAZETTE we have called attention to the value of the various glands possessing internal secretion, and while it is true that certain organs which do not possess internal secretions have been abused therapeutically, it is also true that the glands which we have mentioned are capable of doing as much good as are the others of accomplishing no results.

In the *American Journal of the Medical Sciences* for July, 1897, Kinnicutt, of New York, publishes a paper entitled "The Therapeutics of the Internal Secretions," in which he discusses the results which have been obtained from the administration of thyroid in goitre, insanity, and obesity, and he mentions the various theories which have been advanced as to the method by which it does good. The usefulness of the thymus gland in goitre and other diseases, and the employment of the pituitary body in acromegaly and other lesions supposed to depend upon a disease of this part, are considered. In this article he also publishes a useful bibliography and a carefully prepared list of cases in which adrenal preparations have been employed in Addison's disease, from which it is evident that we have in the adrenal extract practically a specific for this ailment.

### IODOFORM AMBLYOPIA.

In the last few years medical journals, more particularly those devoted to the study of the eye, have had recorded in their pages from time to time interesting cases of parti-

or total blindness produced by the ingestion or absorption from the external surface of some poison which has a peculiar affinity for the fibres of the optic nerve. The information thus obtained has, as is well known to the readers of the THERAPEUTIC GAZETTE, been carefully collated in two monographs, one by Dr. Casey Wood, of Chicago, and a larger one by Dr. G. E. de Schweinitz, of Philadelphia, to whom was awarded the Alvarenga Prize of the College of Physicians for his essay. In this essay we find four cases recorded in which the amblyopia resulted from the absorption of iodoform. Two of them were quite young and two were adult males, and it would seem evident that it requires very large amounts of this drug to produce the symptom which we are considering. According to de Schweinitz a study of these cases would lead us to expect in a typical iodoform amblyopia marked reduction of the central acuity of vision unimproved by glasses, preservation of the peripheral visual field, but a central scotoma at or near the fixation point, and negative ophthalmoscopic appearances and at least gray-ing of the disk with some blurring of the margins. In other words the conditions present in amblyopia from iodoform poisoning are closely allied with those which develop from the excessive use of tobacco or alcohol. Still more recently two interesting cases of amblyopia have been reported by Dr. James W. Russell in the London *Lancet* for June 12, 1897. This gentleman has been in the habit for a number of years of treating his cases of pulmonary tuberculosis with full doses of iodoform, varying from 2 to 10 grains a day. In the course of this series of studies on the influence of iodoform in pulmonary tuberculosis he has met with two cases of iodoform amblyopia.

The first was a man of thirty-two years, who after taking iodoform for several weeks experienced increasing difficulty in reading, and an ocular examination showed that his vision in both eyes was markedly reduced. Stopping the administration of the iodoform resulted in recovery. The other patient was a man of twenty-six years who also received iodoform for a considerable period of time beginning on September 28, 1895. On January 22, 1897, after having taken 10 grains of iodoform for only three weeks continuously he also noticed increasing difficulty in reading and an ocular examination showed marked reduction in vision. An examination by Dr. Wood White, how-

ever, at the Midland Eye Hospital failed to reveal the central color scotoma which is so frequently seen when tobacco produces amblyopia. On leaving off the iodoform vision speedily recovered.

It is interesting to note in this connection that Dr. Russell believes the iodoform treatment of pulmonary tuberculosis to be a very valuable one.

---

*THE INDICATIONS AND CONTRAINDICATIONS FOR THE EMPLOYMENT OF STRYCHNINE IN ALCOHOLISM.*

---

The fact, well known to physicians who are daily brought in contact with inebriates, that strychnine is a useful nervous stimulant to many such patients has within the last few years been utilized by a notorious quack in forming the basis of a method of treatment which he has largely advertised and which has been largely advertised for him by many of the gullible newspapers and the general public. It is simply a deduction from the ordinary laws of therapeutics that any drug possessing such powerful stimulant properties as strychnine ought to prove useful in combating the reaction and depression following acute, subacute, or chronic alcoholic excess. Under its use the tremors, the insomnia, the exaggerated reflexes, the pains in the muscles, the loss of appetite, and certain of the psychical symptoms are materially modified or put aside, and its usefulness seems to be in direct proportion to the acuteness of the alcoholism from which the patient has been suffering. That there is a particular advantage in the so-called nitrate of strychnine over the sulphate of strychnine or any other prepared salt of the alkaloid derived from *nux vomica* does not seem to us to be borne out by practical experience or rational deduction, and as good results should be obtained from the administration of proper doses of the sulphate of strychnine as are said to be derived from the use of the nitrate. It is pointed out by Combemale that there are, however, certain conditions found in alcoholics which should render the physician most cautious in the administration of full doses of strychnine. Particularly is this the case where there are profound alterations in the important and abdominal viscera, as for example advanced pathological changes in the liver, or instances in which there is well developed renal disease. The very condition of glandular inactivity which exists in persons suffering from alcoholism necessarily

renders the elimination of this drug by the saliva, the bile and the urine exceedingly slow, and for these reasons Combemale believes that it is liable to accumulate in the system and produce excessive manifestations later on. He therefore thinks that cirrhosis and nephritis in their chronic forms are both to be considered as partial contraindications to the use of strychnine, or, if the physician still desires to administer this drug, that smaller doses should be employed than would otherwise be used.

#### URETERO-RECTAL IMPLANTATION.

From a fairly comprehensive study of the literature of uretero-rectal implantation Mathes (*Deutsche Zeitschrift für Chirurgie*, 45 bd., 1 u., 2 heft) finds that of fourteen reported cases operated on in accordance with the technique practised by Maydl but two perished, and holds that as greater skill is acquired by surgeons this comparatively low mortality will be reduced still further. Two cases of lateral apposition ended fatally; four of axial apposition—*i. e.*, rectal implantation of the ureter cut across in its continuity—gave two successful results; four cases of implantation facilitated by apparatus resulted in one death, and in one instance the establishment of an abdominal urinary fistula. Of the successful cases, the longest time during which any one had been under observation was fifteen months.

It is evident that uretero-rectal implantation is most likely to be required for the relief of the incontinence which constitutes the most distressing symptom of vesical exstrophy and in the course of operation for the removal of malignant vesical tumors, particularly those primarily affecting the bladder. If the procedure could be shown to be reasonably safe in its immediate effects and to be free from the remote dangers which we have learned to regard as almost inseparable from it, there would naturally be many other pathological conditions which if present would strongly indicate its performance, such for instance as intractable cystitis, vesical tuberculosis, urinary incontinence, or obstinate vesical retention.

The objections which first occur to the mind of the surgeon in considering the operation are: The mechanical difficulty of completing it without infecting the peritoneum and without prolonging the anesthesia beyond the danger point; the irritating effect

of the urine upon the rectal mucous membrane, with resultant proctitis and more or less rectal incontinence; ascending infection along the implanted ureters with the development of fatal pyelonephritis.

The operation is undoubtedly difficult; nor when it is performed through a suppurating bladder is there any certain way of avoiding infection of the tissues involved; yet by careful preparation and judicious use of sterile pads the danger of acute peritonitis can be reduced to a minimum, while practise on dogs and on cadavers will so accustom the surgeon to the general principles of the procedure that much time can be saved.

In the reported cases the urine has not caused proctitis and the anal sphincter has been fairly competent, the patients urinating through it from three to twelve times a day, and often sleeping through the entire night without being disturbed. The sphincter is not always completely competent, however, some of the reported cases habitually soiling the bed and being unable to strain, cough, or pass flatus without an escape of urine and feces.

In the cases of congenital absence of the penis, the ureters opening into the rectum (collected by R. P. Harris, not yet reported), it is noteworthy that the rectum remained free from irritation till the age of puberty; after this proctitis and incontinence developed.

Ascending infection and the development of pyelonephritis, which we have been led to believe both by animal experiments and essays on the human is ultimately inevitable, is apparently due in the main to stenosis and urinary retention; if this can be avoided there is reason to believe that the ureter and kidney may remain healthy. Maydl's operation offers the most rational method of avoiding this stenosis and at the same time preserving the valve which normally exists at the uretero-vesical orifice. Of all the various methods of uretero-rectal implantation by lateral apposition, oblique valvular implantation, and instrumental conjunction, the Maydl method is without doubt the one of choice, and yet even this does not assure against ascending infection, as shown by Mikulicz's case, which died of pyelonephritis four months after operation.

Maydl's operation is thus performed: The patient is placed in the Trendelenburg position, and the case being one of exstrophy, an incision two inches long is made circumscribing the upper third of the exposed vesical mucosa; the latter is then well covered

with sterile pads. The sigmoid flexure is found lying to the left and directly behind the bladder; the portion to be manipulated is walled from the abdominal cavity by sterile pads, sounds are passed into the ureters, the vesical peritoneum is stripped back in the form of two lateral flaps. An oval portion of the vesical mucosa an inch and a quarter by three-quarters of an inch, and containing the ureteral orifices, is cut loose, the ureters with the surrounding cellular tissue are sufficiently freed, till this bladder segment can be brought upward and forward and implanted into the sigmoid flexure, which previously has been stripped of its fecal contents and secured above and below by clamps. The lumen of the gut is opened by a longitudinal incision, the oval bladder segment is turned so that the right ureter is above, and the vesical mucosa is secured to that of the gut by a continuous suture; a second row of interrupted sutures apposes the muscular coat of the bladder to the muscular and serous investments of the bowel; and finally the seat of apposition is covered in by the lateral post-vesical peritoneal flaps held in place by interrupted sutures. The rest of the vesical mucosa is excised, sterile gauze is packed about this implantation, the freshened borders of the recti muscles are approximated as nearly as possible, the belly wound is partly closed by suture with the exception of the space left for drainage, and a soft drainage tube is carried through the anal sphincter.

---

## Reports on Therapeutic Progress

---

### *THE FINAL ANTITOXIN REPORT.*

In another column of this issue may be found the supplementary and final report of the committee appointed by the American Pediatric Association to investigate the efficiency of diphtheria antitoxin. The conclusions deduced by this committee have been sanctioned by the Association and are now given to the world with the full weight of its approval and authority. But that the most critical skeptic shall be disarmed, the methods of this investigation have also been presented in detail.

The solution of two crucial questions has been undertaken. Upon the answers given the claims of antitoxin have been allowed to stand or fall: "(1) What percentage of cases of laryngeal diphtheria recover without oper-

ation under antitoxin treatment? (2) What percentage of cases subjected to operation recover?"

It is proven by the committee's report that in eighty-two per cent. of non-operated cases the patients recovered under the serum treatment, the average percentage of recoveries in the preantitoxin period being ten per cent. To apply even a severer test, let us take the children under two years of age, in which class of patients laryngeal diphtheria is confessedly so dangerous that a mortality approximating one hundred per cent. was formerly regarded as not unusual. Under antitoxin in 356 of these cases only 102 patients were lost, a mortality of less than thirty per cent. With no other evidence than is contained in this statement the most stubborn objector must be convinced.

The investigation of operated cases is equally gratifying; nearly seventy-three per cent. recovered.

A most encouraging feature developed by the committee, but not mentioned in its report, is the fact that 1700 cases of laryngeal croup were treated with the remedy during eleven months. This goes to show how strong a hold serum therapy has taken upon the minds of earnest physicians throughout America.

A very practical suggestion is offered by the committee when a sufficiently potent dose is recommended. As with all untried remedies, the early use of diphtheria antitoxin was very properly tempered by a spirit of caution, but since a purer and more concentrated product is now furnished, experience would suggest a larger and more efficient dosage.

The highest commendation should be accorded the American Pediatric Association for so persistently adding line upon line and precept upon precept until a verdict of "proved" has been established beyond peradventure. The final word has been spoken—a fact is before us.—*Medical News*, May 15, 1897.

---

### *THE USE OF CONVALLAMARIN IN CHLOROFORM NARCOSIS.*

LEWENBERG has carried out a series of experiments with dogs in which he has given full doses of convallamarin for the purpose of combating the arrest of circulation and respiration caused by the chloroform, with the result that he believes this remedy is of value in preventing or remedying this accident.

*A PRESCRIPTION FOR PRURITUS ANI.*

According to *La Presse Médicale Belge* of April 25, 1897, the following prescription is useful:

- ℞ Powdered camphor, 30 grains;  
Oxide of zinc, 1 ounce;  
Bismuth, 1 ounce;  
Talc, 1 ounce.

This powder is applied by means of absorbent cotton, the part which itches having been first painted by a twenty-five-per-cent. solution of nitrate of silver, after which a suppository of cacao butter and extract of belladonna may be used.

*DOSAGE FOR CHILDREN.*

The *Journal des Praticiens* of March 20, 1897, gives the following information in regard to caffeine, which is to be considered a heart tonic and stimulant to the nervous system and a diuretic. Hypodermic injections of the benzoate of caffeine may be given in the following formula:

- ℞ Caffeine,  
Benzoate of sodium, of each 15 grains;  
Distilled water, 2½ drachms.

The caffeine will not be completely dissolved without heat. A syringe containing twenty to thirty minims of this solution may be used for this injection. The dose of caffeine for the age of the child is as follows: For a child up to fifteen months, one to two grains a day; fifteen months to three years, three to four grains; three to five years, four to five grains; five to ten years, five to eight grains.

Caffeine may be given by the stomach in the following solution:

- ℞ Syrup and distilled water, of each 6 drachms;  
Rum, 2 drachms;  
Citrate of caffeine, 15 grains.

A small teaspoonful of this may be given two or three times a day.

Calomel, which is to be employed in children for its influence upon the liver and as an intestinal antiseptic, is to be used as follows: As a purgative in one single dose it should not be given to a child up to six months. From six months to fifteen months the dose is one to two grains; fifteen months to three years, two to three grains; three to five years, three to five grains; five to ten years, five grains.

As an intestinal antiseptic the dose ought to be very small. It should not be given before six months. From six to fifteen months,  $\frac{1}{100}$  to  $\frac{1}{50}$  of a grain may be given at hour

intervals; from fifteen months to three years half a grain may be given three or four times at hour intervals; three to five years, three-fourths of a grain three or four times at hour intervals; five to ten years, one grain two or three times at hour intervals.

Calomel is an exceedingly useful intestinal antiseptic, but should not be repeated on consecutive days. It is best given mixed with a little sugar or sugar of milk.

*THE TREATMENT OF LOCOMOTOR ATAXIA.*

In the *Revue de Thérapeutique* of May 1, 1897, ERB, of Heidelberg, has an article upon this subject, which, as we all know, is one usually considered barren of therapeutic possibilities. After pointing out that syphilis is the chief cause of the disease and that venereal and alcoholic excess are other causes, he speaks of the necessity of treating nervous syphilis in its earliest stages not only by ordinary methods, but by the patient visiting hot springs, where active antisypilitic treatment may be carried on thoroughly. At the same time tonics, such as quinine, iron, and nux vomica, may be administered and various hydrotherapeutic measures instituted. If the iodides are employed they should be given in doses amounting to forty-five to sixty grains a day at least. The principal indication for the employment of the iodides consists in tertiary complications affecting the skin, mucous membranes, or the bones, and in cerebral syphilis; or that form in which there are violent shooting pains and the rapid development of symptoms of ataxia, probably due to peripheral neuritis. Everything should be done to avoid nervous excitation of the patient. In a few cases the nitrate of silver continued over long periods of time, then stopped, and then readministered, seems to be of value. Thus one-fourth of a grain may be given each day associated with the extract of nux vomica. The author has not obtained results from the administration of ergot. Arsenic deserves a trial, but the bromides are not to be employed. The following prescription is very useful as a tonic:

- ℞ Lactate of iron, 45 to 50 grains;  
Extract of cinchona, 60 to 75 grains;  
Extract of nux vomica, 5 to 10 grains;  
Extract of gentian, sufficient quantity.

To be made into 100 pills. Two or three of these are to be taken after each meal.

When baths are taken they should be neither too hot nor too cold, but of such

a character as to be tonic. For fulgurant pains the part affected may be wrapped in hot cloths, or small compresses wet with ether or chloroform may be employed; or, instead, a spray of chloride of methyl or a mustard plaster may be used. Frictions with chloroform or with liniments containing opium and belladonna may also be employed. In some cases, too, the coal-tar products in full doses give marked relief. In very grave cases it is absolutely necessary to secure relief by injections of morphine. For laryngeal crises we are to employ inhalations of chloroform and ether or a spray of cocaine. Other persons have recommended galvanization of the neck, particularly of the pneumogastric and the cervical sympathetic. For anovesical crises a powder composed of acetanilid, one of the bromides, and codeine or morphine is useful. To combat the paresthesias and anesthetics the cathode of the faradic or galvanic current may be applied to the part and stroking movements employed.

For the atrophy of the optic nerve mercury and iodide medication is necessary. Full hypodermic injections of strychnine may be given, tincture of iodine may be used externally, or the actual cautery applied at the back of the neck. Erb quotes Galezowski as recommending injections over a long period of time with cyanide of gold or the cyanide of mercury.

Should ataxia develop rapidly the patient must be made to take absolute rest, but should the ataxia be chronic the method of Fraenkel, based upon systematic exercise, possesses great advantage. For vesical troubles suspension perhaps does the most good, although hydrotherapy and strychnine are to be remembered as other remedial agents.

Finally, the following points may be given as the chief aim in the treatment of tabes: Active antisyphilitic treatment if the indication exists, the use of tonics, and electricity; hydrotherapy in its various tonic forms, the use of electrotherapy and suspension, care being taken not to neglect symptomatic treatment. Later, if the indications still exist for active antisyphilitic treatment it is to be used, although such good results cannot be expected from it. Careful regulation of the diet should be insisted upon, and hydrotherapy, electricity, with gymnastics, suspension, and psychical treatment should be utilized. If the disease is very far advanced and the patient is much incommoded in his movements, it is important to maintain his mental

tone by every encouraging method that we possess, and to use medication which will combat the disagreeable or painful symptoms.

#### THE MEDICAL TREATMENT OF PYELITIS.

In the *Bulletin Général de Thérapeutique* of April 30, 1897, ROBIN, after pointing out that this condition is usually regarded as one requiring surgical measures for relief, asserts that there are certain conditions in which medical treatment is of great value. In the first place great attention should be paid to the condition of the skin, the functions of which should be aided in every possible way, and an endeavor made to bring blood to the part by relieving the kidney. For this purpose the following liniment, used with active friction, may be valuable:

- R Tincture of cinchona,  
Spirit of camphor, of each 3½ ounces;  
Menthol, 30 grains;  
Tincture of nux vomica, 6 drachms.

Use as a liniment.

In regard to food, an absolute milk diet should be insisted upon and continued as long as possible, a pint being given every three hours, to be drank slowly in small sips. The tolerance of this diet, when given at proper intervals and in small quantities at a time, is quite extraordinary. If the patient becomes exceedingly tired of the milk diet, then we may allow broths and various farinaceous substitutes, but heavy foods should be carefully avoided. When waters are employed they should be from mildly alkaline springs. The medical treatment can be divided into three parts, namely: The use of balsams, of revulsives, and of astringents. As types of the balsamic method of treatment may be mentioned benzoic acid with the benzoate of sodium, both of which did these cases much good. From fifteen to sixty grains in the twenty-four hours is usually a sufficient maximum dose. There is no use in giving larger doses than this or continuing it for a very long period of time. The benzoic acid or benzoate of sodium may be given in capsules, or solution with syrup of orange flowers, or the following balsams may be used as adjuvants: Balsam of tolu, copaiba, eucalyptol. Or we may use turpentine 1½ drachms, powdered camphor 1½ drachms, extract of opium 2 grains, extract of aconite root 4 grains; to be made into 60 pills, and three pills given each day.

In the way of counter-irritation or re-

vulsive treatment during the acute stage of the pyelitis we may apply counter-irritation by means of a hot iron; but we should not employ cantharides to produce a blister, lest some of it may be absorbed and cause kidney trouble; or we may employ rhatany, tannin, or gallic acid associated with opium.

Internally we may need to employ anti-septic substances such as salol. Should hematuria develop the following prescription may be useful:

- ℞ Ergotin, 1 drachm;  
Gallic acid,  $\frac{1}{2}$  drachm;  
Turpentine, 1 drachm;  
Aromatic elixir, 4 ounces.

One or two teaspoonfuls every two or three hours.

Should there be much pus in the urine an absolute milk diet and quinine in large doses is of value. Should pain become a serious symptom it may be relieved by rubbing with the following liniment and by the use of an opium suppository:

- ℞ Camphor liniment, 1 ounce;  
Fluid extract of opium,  
Fluid extract of belladonna,  
Fluid extract of hyoscyamus, of each 30 minims;  
Chloroform,  $\frac{1}{4}$  ounce.

Of the mineral waters which the patient should drink may be mentioned Vichy and Contrexeville. Sometimes Carlsbad water is useful.

#### A PRESCRIPTION FOR NEURALGIA.

The *Revue de Thérapeutique* of May 1, 1897, gives the following prescription:

- ℞ Extract of hyoscyamus, 4 grains;  
Extract of valerian, 4 grains;  
Hydrochlorate of morphine, 1 grain.

Make into four pills; take one to four in twenty-four hours.

#### THE TREATMENT OF PULMONARY EDEMA.

In the *Journal des Praticiens* of May 8, 1897, HUCHARD, after discussing the history, etiology, and pathology of this affection proceeds to consider its treatment. He recognizes the fact that there is usually present great dilatation of the right ventricle, feebleness of the heart muscle, and high tension in the pulmonary artery; that there is usually a disorder of cardio-pulmonary innervation, and that in very many cases there is also secondary toxemia due to renal disease or inactivity. For the tendency to failure of the right ventricle he suggests digitalis, which many of us have already applied with advantage. General venesection may be employed, or wet cups may be applied over the

thoracic region or the region of the liver or kidneys. For sudden cardiac failure he highly recommends hypodermic injections of caffeine and camphorated oil, which may be advantageously substituted by ether or some similar rapidly-acting stimulant. For the purpose of combating the disordered innervation of the cardiac pulmonary apparatus and the relaxed condition of the bronchial tubes and diaphragm, he believes that full hypodermic injections of strychnine is the best treatment, and he reminds us that as long ago as 1879 he highly recommended faradization or galvanization of the vagus nerve for the purpose of overcoming the vascular relaxation. In terminating his article he points out that atropine has been found an exceedingly valuable remedy, a fact which has certainly been well authenticated by American practitioners. The camphorated oil which he employs is prepared according to the following formula:

- ℞ Sterilized olive oil, 1  $\frac{1}{4}$  ounces;  
Camphor, 2  $\frac{1}{4}$  drachms.

Inject three or four hypodermic syringefuls a day.

Huchard states that the injections are not painful. For the purpose of producing diuresis he orders an exclusive milk diet and gives from twenty to forty-five grains of theobromine a day.

Should the tendency to pulmonary edema develop in persons suffering from arteriosclerosis, he believes that the iodides are useful. With this advice, however, the editor of this journal must take exception, unless they are employed with the greatest caution.

#### DOSAGE FOR CHILDREN.

The *Journal des Praticiens* of May 8, 1897, gives the following dose-table:

Cherry-laurel water, which is useful as a sedative, is not to be given to a child under three years. From three to five years thirty to sixty minims may be given each day, and from five to ten years from sixty to one hundred and twenty minims may be administered.

Of calcined magnesia, used as an antacid and laxative, up to fifteen months the child may receive fifteen to thirty grains a day; three to five years, forty-five grains to a drachm a day; and from five to ten years, one to one and a half drachms a day.

In regard to the administration of quinine to children, the best preparation to employ is the hydrochlorate. The doses for different

years are as follows: Up to one year, one to three grains a day; one to two years, three to four grains; two to three years, four to five grains; three to four years, five to seven grains; four to seven years, five to ten grains; seven to ten years, eight to twelve grains.

Quinine may be given mixed in a confection with honey, or in pill or cachet. Should the drug be given by rectal injection the dose should be doubled. It may be administered by the rectum in the following solution:

- ℞ Hydrochlorate of quinine, 4 grains;  
Warm infusion of chamomile, 2 ounces;  
Sydenham's laudanum,  $\frac{1}{4}$  drop.

#### THE TREATMENT OF CORYZA OR HAY-FEVER.

The *Journal de Médecine de Paris* of May 9, 1897, recommends the mucous membrane be touched with the following solution:

- ℞ Hydrochlorate of cocaine, 3 grains;  
Boiled water,  $\frac{1}{4}$  ounce;  
Neutral glycerin, 30 minims.

Or use the following ointment applied to the mucous membrane by means of smearing it on small tampons of absorbent cotton:

- ℞ Hydrochlorate of cocaine,  
Thymol, of each 3 grains;  
Subcarbonate of bismuth, 2 ounces;  
Vaseline, 1 ounce.

Or the following powder may be insufflated into the nostril:

- ℞ Powdered boric acid, 30 grains;  
Salicylate of sodium, 40 grains;  
Hydrochlorate of quinine, 3 grains.

Or any of the following may be used:

- ℞ Naphthalene in impalpable powder, 6 drachms;  
Boric acid (impalpable powder), 6 drachms;  
Powdered camphor, 15 grains;  
Extract of violets, 15 grains;  
Essence of roses, 20 drops.
- ℞ Menthol, 5 to 10 grains;  
Powdered boric acid,  
Powdered chalk, of each 40 grains;  
Hydrochlorate of cocaine, 7 grains.
- ℞ Menthol, 6 grains;  
Salicylate of bismuth,  
Sugar of milk, of each 75 grains.

#### A SOLUTION FOR SEA-SICKNESS.

The *Journal de Médecine de Paris* of May 9, 1897, quotes the following as being efficacious:

- ℞ Chloroform, 45 minims;  
Alcohol,  $\frac{1}{4}$  ounce;  
Aromatic elixir,  $\frac{1}{2}$  ounce.

Twenty to forty drops as needed.

#### TREATMENT OF WHOOPING-COUGH BY RESORCIN.

The *Medical Chronicle* for May, 1897, quotes from one of the French journals the following therapeutic point:

Dr. ROSKAM, in 1890, communicated the result of the treatment of twenty-five cases of whooping-cough by application to the glottis of a two to three-per-cent. solution of resorcin. Following the directions of Dr. Moncorvo, who suggested the method, he employed at first a ten-per-cent. solution of cocaine before applying the resorcin solution. He soon found it preferable to omit the cocaine application, as it occasioned severe spasms, and employed the resorcin solution alone. Eighteen of the twenty-five children were cured in about ten days. Three children, to whom the treatment was given for a few days only, and whose cough had ceased, had on the eighth day a relapse with violent cough. They were cured, however, in three weeks. Two cases proved refractory to the treatment; and two children who were in a very low condition died in spite of the treatment, which, however, diminished the number of attacks of coughing.

To confirm these results, Dr. Roskam has, since 1890, treated 290 children affected with whooping-cough by resorcin applications. Usually treatment was instituted during the first fortnight of the disease, but sometimes at a later stage. Although three of the cases were in a very low condition, he did not lose one of this series of cases.

In 200 patients cure was brought about before fifteen days had elapsed. Seventy were cured before the twenty-fifth day after commencing treatment, and eighteen before the thirtieth day. Lastly, two patients, a brother and sister, whose paroxysms of coughing had ceased after twelve days, had relapses on the eighteenth and twentieth days; after fifteen days' renewed application of the resorcin solution they completely recovered.

Dr. Roskam believes that children under two years of age are particularly susceptible to the action of resorcin. In the immense majority of cases under one year, cure was obtained in about eight days after commencing treatment. This fact may be due to the facility with which the applications may be made in very young children. Dr. Roskam thinks it advisable to delay the resorcin applications till the congestive period at the onset has passed and the paroxysms of coughing have become markedly evident.

Children under a year were treated with a

two-per-cent. solution. Those from one to two years had first a solution of two-per-cent., then one of three-per-cent. strength. Above two years of age a three-per-cent. solution was used. The applications were made every four hours during the day, from 6 A.M., and once or twice at night.

After two or three days' treatment—sometimes even after one day—the digestive functions improve. The patient eats and digests well, and becomes more lively. In five to six days the general condition becomes almost normal. The paroxysms of coughing still persist, but they are shorter, easier, and less frequent, especially during the daytime.

When the applications have been made for ten to twelve days it is advisable to suspend the treatment, even if the patient still has attacks of coughing. Very often cure is established; if not, after an intermission of five to six days the applications may be repeated for some days.

Dr. Roskam believes in allowing the children to have plenty of fresh air, if they have no fever. He has no confidence in pretended antiseptic fumigation of rooms, which often renders the air irrespirable and increases the number of the attacks of coughing. He points out how necessary it is to impress the parents that the cure of the children depends on the care with which they apply this method for some days. Usually, after a few days, the children submit readily to the applications.

#### THE TREATMENT OF WHOOPING-COUGH.

EROSS' observations were made in 874 cases; 832 were out-door patients; the remainder were seen in private practise.

The majority of the children were over two years of age; fifty-two were nurslings. The internal medication comprised the use of bromide of potash, tincture of belladonna, codeine, quinine, antipyrin, phenacetine, antifebrine, and bromoform. Resin of benzoin was insufflated into the nose. In the majority of cases the treatment was begun when the paroxysmal stage was at its height.

Bromide of potash and tincture of belladonna produced the least benefit. Quinine in some cases worked well—that is, when it could be given long enough and in sufficient doses. Small children refused to take it. It also acted unfavorably on the general well-being of the child, and the appetite under its use diminished. Of far greater value were antipyrin, antifebrine, and phenacetine, which were used in several hundred cases. The

drugs were given in syrup, coffee, or water. Unfavorable results, such as depression and prostration, never followed the administration of any of the coal-tar preparations. Phenacetine seemed to possess the least value; but from twelve to fifteen per cent. of the patients showed signal improvement under its use. Antipyrin gave the most favorable results. Thirty-five per cent. of the cases showed marked improvement.

None of the remedies mentioned above produced such an immediate change for the better, in convulsive attacks, as bromoform. Under its use vomiting and other complications were almost unknown. The convulsive character subsided almost entirely. The beneficial effects were noted in from forty-eight to seventy-two hours.

The insufflation of resin of benzoin gave the best results of all the remedies used. In sixty per cent. there was a marked improvement in the severity of the paroxysms, with a shortening of the course.

The beneficial effects were chiefly noted in diminishing the number of the paroxysms, the severity being controlled in a lesser degree. When no improvement follows four or five days' use of the insufflations it is best to discontinue the treatment. The powder must be blown not only into the nose but into the pharynx as well.—*Archives of Pediatrics*, May, 1897.

#### THE TOXIC EFFECTS OF IODOFORM DRESSINGS.

In the *American Gynecological and Obstetrical Journal* for March, 1897, McLEAN of New York concludes a paper on this topic as follows:

The toxic effects of iodoform may be conveniently classed in three groups:

1. Cutaneous irritation: Eruptions of the skin in erythematous or eczematous form associated with the pruritus of urticaria.

2. Cerebral disturbances: Headache often very marked; delirium more or less active; melancholia, hallucinations; the pupils occasionally dilated, but more often contracted and motionless; the pulse decidedly accelerated, running early up to 135 to 150 per minute; quality rather small and wiry; rapid increase of temperature.

3. Syncopal or asthenic form of poisoning: Patient overcome with dizziness, mental confusion, great lethargy; weak, rapid pulse; some paralysis of the sphincters, death coming sometimes suddenly by heart failure.

Inasmuch as we have shown that a peculiarity of the drug is its rapid absorption and its slow elimination, it is well to draw careful conclusions as to the significance of certain symptoms occurring in operative cases where iodoform plays a prominent part.

By so doing we may spare our patients much unnecessary suffering and not a little danger, and ourselves a secret agony which few conscientious men have been able to escape.

#### STROPHANTHUS: A CLINICAL STUDY.

WILCOX in the *American Journal of the Medical Sciences* for May, 1897, concludes an interesting clinical paper on this subject in the following words:

Fraser presents a most interesting study of the action of strophanthus upon the heart, finding it eight times more powerful than adonidin, scillitoxin, or erythrophlein; twenty times more than helleborein, thirty times more than convallamarin, three hundred times more powerful than caffeine. On the contrary, upon the blood-vessels digitalis acted fifty times stronger than strophanthus.

The advantages which strophanthus possesses over digitalis may be summed up as: (1) greater rapidity, modifying pulse-rate within an hour; (2) absence of vasoconstrictor effects; (3) greater diuretic power; (4) no disturbance of digestion; (5) absence of cumulation; (6) greater value in children; and (7) greater safety in the aged.

When we consider that although digitalis has been in use since 1785 in the treatment of cardiac disease, it is only within the past ten years that it may be truly said that its administration was productive of uniformly excellent results. That this is so is undoubtedly due to the fact that the greatest danger from its use—namely, the marked vasoconstriction—has been to a considerable degree obviated by the common practise of the co-incident administration of a nitrite.

Strophanthus was first brought to the notice of the French Academy of Medicine in 1865, but its first practical demonstration as a valuable heart remedy came twenty years later, when Fraser published the results of his long-continued and patient researches. With the wider and more rapid dissemination of knowledge which obtains at the present day, we may hope that within a comparatively few years we may have strophanthus used as carefully as is digitalis to-day. That it possesses distinct advantages over the latter drug is undoubted, and it is equally certain

that it is free from the greatest danger which the use of digitalis entails—namely, vasoconstriction.

We may say that success in the administration of strophanthus requires: (1) An active, well-made preparation from a reliable source; (2) avoidance of its use in the fully- or over-compensated hearts of those who present advanced muscular degeneration or mechanical defects of high degree; (3) the use of not too large or too frequently repeated doses. From my own observations the dose of five drops of a reliable tincture three or possibly four times a day is sufficient.

In conclusion, he believes that, considering the limitations just enumerated, strophanthus is the drug of choice in:

1. All cases in which we wish to establish compensation.
2. All cases of arterial degeneration in which a remedy which causes more energetic cardiac contractions is required.
3. All cases of cardiac disease where diuresis is necessary.
4. All cases of weak or irritable hearts.
5. All cases of cardiac disease in childhood or old age.

#### THE USE OF METHYLENE BLUE IN ALBUMINURIA.

In the *Journal des Praticiens* of May 22, 1897, LEMOINE of Lille makes a report upon this drug when used for the purpose of decreasing albuminuria. He believes that it exercises a very beneficial influence upon the kidneys, particularly in cases of chronic nephritis. The dose which he gives varies from three to five grains a day.

The following case may be cited as an instance of the result of this treatment: A man of fifty-eight years, suffering from chronic Bright's disease with renal congestion and albuminuria, was admitted to the hospital. On the 25th of February he was passing six grammes of albumen a day. He was given a modified milk diet and treatment with alkalies and tannin. Shortly afterward he was placed upon methylene blue in the dose of four grains a day. On the 3d of March he was passing four grammes of albumen; four days later he was passing two grammes; and on March 10 he was passing twenty grains.

The author cites other cases as illustrative of the good results which he has obtained in his opinion from this treatment; and he claims that while there is a decrease in the

albuminuria, there is apt to be an increase in the quantity of urea which is eliminated. In one case of chronic albuminuria with death due to erysipelas, the patient had been receiving methylene blue for several days. At the autopsy the kidneys were found enormously enlarged and contained cysts and gave evidence of sclerotic change. The methylene blue had stained the secreting portions of the kidney, but the fibrous portions had retained their natural color. He believes that this is an indication of the fact that methylene blue exerts a selective influence upon secreting epithelium of the kidney. He does not think that if pure methylene blue is used there is any danger of it producing cystitis. Copious draughts of liquids should be taken in order to flush the kidneys and prevent the drug from irritating the stomach.

---

*THE AMERICAN PEDIATRIC SOCIETY'S  
REPORT ON THE COLLECTIVE INVESTIGATION OF THE ANTITOXIN  
TREATMENT OF LARYNGEAL  
DIPHTHERIA IN PRIVATE  
PRACTICE, 1896-1897.*

The committee recommends: Antitoxin should be given at the earliest possible moment in all cases of suspected diphtheria. Of the quality of the products on the market some have, by test, been found to contain one-half to one-third the antitoxin units stated on the label. Select the most concentrated strength of an absolutely reliable preparation.

All cases of laryngeal diphtheria, the patient being two years of age or over, should receive as follows: First dose, 2000 units at the earliest possible moment; second dose, 2000 units twelve to eighteen hours after the first dose, if there is no improvement in symptoms; third dose, 2000 units twenty-four hours after the second dose, if there is still no improvement in symptoms.

Patients under two years of age should receive 1000 to 1500 units, the dose to be repeated as above.

---

*A PLEA FOR THE LARGER USE OF ERGOT  
IN OBSTETRICS.*

THOMAS MORE MADDEN in the London *Lancet* of May 29, 1897, thinks that the conditions and circumstances under which ergot may be employed in obstetrics may be briefly stated, although, as will be seen, the writer ascribes a wider range of utility to ergot in midwifery practice than is generally con-

ceded. Nevertheless the writer presumes to observe that his views are the result of actual clinical experience which it may not be easy to disprove by any merely theoretical objections, however strongly expressed. Judging from the recent literature of this subject it apparently is not superfluous to premise that to use any preparation of ergot safely and effectively in the labor cases referred to it is essential (1) that the presentation should be natural or cranial, except in some instances of breech presentation, in which it may possibly be necessary to deal at once with uterine inertia; (2) that there should be no marked disproportion between the fetus and the mother, or any other physical impediment to delivery in the genital tract; (3) that the os uteri, if not previously fully dilated, should be so dilatable as to allow of speedy extraction by the forceps when necessary; and (4) that the preparation selected, the dose, and the method in which it is employed, should be well calculated to produce the required effect.

Subject to the foregoing conditions, ergot may with utility be employed when actually indicated and judiciously administered either before, during, or after the second stage of labor. That is to say, it may be given before the full dilatation of a dilatable os in some instances of long delay from uterine inertia in which there is imminent danger to mother or child, or risk of subsequent flooding from further protraction of the case. During the second stage it may be employed in labor rendered abnormally tedious by deficiency of uterine action or otherwise complicated, and in which the presentation is natural and no other impediments to delivery exist, or for the prophylaxis of apparently impending flooding. During the third stage ergot may be resorted to for the expulsion of the placenta when retained by inertia, or for the arrest of loss of blood. After delivery this ecboic may be employed either immediately to check or prevent hemorrhage, or subsequently to produce tonic or permanent contraction, and, by sealing up the uterine vessels, lessen the liability to bacteriological invasion or sepsis; or else at the same time it may be exhibited for the purpose of expelling clots from the womb and so arresting after-pains. Lastly, in the majority of multiparous patients ergot may be administered during the puerperal period with the object of stimulating the muscular tonicity of the uterus, accelerating the process by which its return to a normal condition

after parturition is effected, and thus obviating the future possibility of chronic subinvolution.

To produce the desired effects in the cases above referred to it is obviously necessary that ergot should be administered in the form, dose, and method best calculated to secure speedy and permanent contraction of the muscular tissues. Under no circumstances, therefore, should ergot be given in obstetric practise in those small, utterly inefficient, and frequently repeated doses that have been recommended by several modern authorities, but which in the author's opinion are calculated to do more harm than good by producing irregular and evanescent waves of muscular contractility instead of that firm, regular, and tonic uterine contraction by which alone persistent inertia may be overcome, the fetus or the placenta expelled, post-partum hemorrhage prevented or arrested, retained clots and membranous or placental débris dislodged, and subsequent sepsis or still later subinvolution may be obviated. With these objects in view, in Madden's early days an extemporaneous infusion of the crude, freshly powdered drug was most generally employed, and though troublesome to prepare and nauseous to take, was of unquestionable ecboic activity.

#### THE TREATMENT OF PERITYPHLITIS.

The London *Lancet* of May 29, 1897, in speaking editorially of this subject, says it may be affirmed without fear of contradiction that the value of prompt surgical intervention in acute abdominal disease can hardly be more clearly shown than in the treatment of perityphlitis, now universally admitted to depend on inflammation and ulceration of the appendix vermiformis. It has been proved in numberless instances that by such intervention peritonitis has been averted or checked in its spread, and there can be no question that lives have been saved by this means. On the other hand, it is equally certain that lives have been sacrificed by unavoidable delay in having recourse to this radical measure. In spite of this general feeling of the necessity for resort to surgical aid, and the frequency with which it is sought, it is yet surely true that in the days before there was any idea of invoking the aid of surgery the disease was not characterized by any very great mortality. The lines of treatment were simple, and under their adoption the acute manifestations passed

gradually away, in the majority of cases perhaps never to return, though in a certain proportion of cases symptoms recurred at intervals under slight provocation. It is true, however, that this fortunate result was varied by cases where peritoneal or extra-peritoneal suppurations placed life in jeopardy, or were responsible for a long and weary illness that only ended in death; and there were also the cases of perforative peritonitis, which hardly come under the category that we are now considering, but fatalities from which may certainly be obviated by surgical procedure.

The impunity with which the surgeon can now fearlessly lay open the abdomen, and the satisfaction felt at the discovery of a gangrenous appendix and its removal, has perhaps rather led us to despise the *vis medicatrix* that must in past days have often effected a radical cure. It all turns on the old question whether the slow and somewhat hazardous processes of Nature are not better replaced by the rapid measures of the art of surgery, the whole aim and purpose of which is to anticipate the development of greater ill, which may eventuate if the disease is left to itself. We have no intention here to discuss the indications for interference; we might even admit that the operation can be justified in every case, even the mildest. But as exhibiting the other side of the question, we would draw attention to a paper by Dr. Kleinwachter, of Breslau, a former clinical assistant of the late Professor Biermer, who relates the experiences of the medical treatment of perityphlitis in that physician's wards in the years 1874 to 1889—that is, in the pre-chirurgical days of the treatment of this affection. Dr. Kleinwachter observes that in spite of the gratitude owing to surgeons for their researches on the subject, and the striking results that often ensue from their operations, it is difficult for the physician to admit that a disease which can in the majority of cases resolve without the aid of surgery should come to be considered as falling exclusively into its domain. He suggests that the only way to prove the necessity for this transference is by comparative statistics, and for that reason he has collected and tabulated details of the cases in Professor Biermer's clinic during the period named, none of which were treated otherwise than on medical principles. These principles aim at obtaining complete rest of the intestinal canal by the strictest attention to rest of body and to diet, as well as by the administration of opium. In more detail he describes the

treatment as consisting in keeping the patient absolutely at rest in bed, and the relief of the pain and fever by the application of iced water compresses or an ice-bag to the abdomen, the cold bag being replaced by warm applications as soon as the fever subsides and signs of exudation appear. From the outset opium or morphine is administered, no matter whether there be diarrhea or constipation. Professor Biermer took as guides for the continuance of the opium treatment the presence of pain and tenderness and abdominal distention, for whenever the colic recurred the patient was allowed to have another dose. Dr. Kleinwachter has known the administration of opium to have been continued for fourteen and even twenty-five days, and states that the resulting constipation was well borne, whilst other disagreeable symptoms, as hiccough, vomiting, and cough, were mostly controlled by the drug.

Restriction to a fluid diet of minimal proportions is a necessity; where there is a tendency to vomit and much thirst only ice is allowed, and gradually rice-water, lemonade, diluted red wine, then thin broths, and finally milk. The opium can be omitted when pain no longer recurs and the abdominal tension does not increase, but it must be resumed on the slightest return of pain. The bowels usually begin to act spontaneously from the fourth to the ninth day, and after two or three such actions they must be assisted by enemata or mild saline aperients, as bilin, or Carlsbad water. Much care is to be observed in the diet subsequently to the attack, and the patient should always be able to have recourse to a dose of opium, if at any time afterwards there is a return of colic. Should there remain any resistance in the ileo-cæcal region, due probably to adhesions or residues of exudations, it is recommended to continue the use of wet compresses and of warm baths. If the condition of the patient grows worse, the abdominal distention increases, the breathing quickens, and the pulse becomes more rapid, then the opium is still further pushed or replaced by morphine, the force of the heart being maintained. Professor Biermer was careful to refrain from large injections in lavage of the stomach or intestinal puncture to relieve distention.

If the foregoing be a correct account of Professor Biermer's practise, it will be seen to have mainly relied upon the prescription of opium, carried to an extent now rarely considered advisable, and that, too,\* manifestly when the case was assuming the fea-

tures of general peritonitis. At the present day in most acute inflammatory abdominal diseases the free use of opium is rather deprecated, as tending to mask the symptoms and delay the intervention of surgery until all reasonable prospect of relief by this latter means is past. It will therefore come as a surprise to many to learn that out of a total of 112 perityphlitic cases (three of which relapsed) so treated in Professor Biermer's clinic, only two died—a case-mortality of 1.78 per cent. One of these fatal cases had the ordinary characteristics of perityphlitis and had progressed so far that the opium was left off, when on the following day, after a sudden evacuation, a fatal coma supervened. The other, severe from the first, succumbed on the ninth day to diffuse peritonitis. All the rest recovered. Particulars were obtained of the after-history (up to 1889-90) of seventy of those patients who left the hospital—namely, of sixty-one out of ninety-eight who left it “well,” and nine out of twelve who were discharged “unrelieved.” Relapses had occurred in seventeen, or 24.3 per cent., and two of these were fatal. In five cases many recurrences had taken place, but in not a single one had the relapse supervened later than two years from the date of the primary attack.

These figures, which it must be remembered are culled from the practise of one hospital physician, and therefore may be taken as being based on a consistent line of treatment, are surely deserving of attention; for although there is, even amongst the most successful operators, a commendable recognition of the fact that in the majority of cases of appendicitis resolution may occur, there is still great uncertainty as to how far it is either right or justifiable to pursue purely medical treatment. The position is one of great delicacy and difficulty; for in contrast to these figures we have the statistics of St. Thomas's Hospital, given by Dr. Hawkins in his excellent monograph, which show that the general mortality from appendicitis amongst 264 cases was fourteen per cent., or twenty-six per cent. of those terminating in abscess, and seventy-five per cent. of those ending in general peritonitis. It is possible that had Dr. Kleinwachter been able to trace out all Professor Biermer's patients the mortality from recurrence would have been found to have risen, and each such case may be reckoned as one that might have been saved by a primary operation. But then, as in many the primary attack might not have

been of the severity held to justify such interference, no comparative conclusion regarding medical and surgical treatment can be drawn from them. And since few, if any, advocate the removal of the appendix as a routine measure, we seem to be unable to institute any comparison—at least, a statistical one—between the surgical and the medical method of dealing with the disease. The claim for Professor Biermer's treatment must rest not merely on a lower death-rate, but on its favoring resolution and averting supuration, which is in some cases the inevitable outcome of the lesion of the appendix. It requires more courage to act up to this belief than most of us possess, now that we have become more intimately acquainted with the nature of the underlying lesion, and the possible risk entailed by delay in having recourse to surgery. Therefore, although we cannot but admire the remarkable results which we owe to the industry of Dr. Kleinwachter, we the more incline to the opinion expressed in a recent text-book: "As soon as the diagnosis of appendicitis is established—indeed, pending its settlement—a competent surgeon should be associated with the physician, for the reason that in the vast majority of cases operative treatment is sooner or later demanded, while the hour for such treatment is best settled by daily conference."

#### RESECTION OF THE GASSERIAN GANGLION FOR REBELLIOUS FACIAL NEURALGIA.

MARCHANT and HERBERT (*Revue de Chirurgie*, April 10, 1897, p. 286) report two cases of extirpation of the Gasserian ganglion for the relief of rebellious neuralgia, and they analyze ninety-three additional cases collected from the literature. Among the whole number there were seventeen deaths (17.8 per cent.). In sixty-six the temporal course was followed, with eleven deaths (12.12 per cent.), three of which were open to doubt; in twenty-nine the pterygoid course was followed, with six deaths (20.6 per cent.). Among fifteen cases of complete extirpation of the ganglion there were five deaths, three of which were open to doubt (13.13 per cent.). Among sixty cases of incomplete extirpation there were eight deaths (13.13 per cent.). Among fifteen cases of simple resection of the painful branches there was but a single death (a mortality of 6.66 per cent.). From a study of the literature of the subject the conclusion is reached that certain rebellious

facial neuralgias originate in the Gasserian ganglion, and the only treatment of these cases consists in destruction of the ganglion. When no appreciable lesion of the ganglion existed and its removal was none the less followed by a disappearance of the neuralgia, this result is to be explained by the destruction of a nervous center containing neurons or nervous cells whose prolongations only are affected by simple section of the nerve. The temporo-sphenoidal course is the best to follow for the removal of the ganglion. The finding of one of its branches, and especially the inferior maxillary, in the oval foramen constitutes one of the most certain guides for the detection and seizure of the ganglion. The ganglion may be completely extirpated. Commonly the extirpation is incomplete, and the ganglion is finally destroyed by curetting and crushing. Often only its branches have been resected. Hemorrhage, wounding the nerve, and cerebral compression are the immediate operative accidents to be feared. Secondly there may be infection, hemorrhage, iodoform intoxication, ocular disturbances, and otitis. As an immediate result of the operation there is a cessation of pain and also an abolition of general sensibility in the distribution of the three branches of the nerve, and especially in the second and third branches; but this does not persist long. Taste, smell, hearing and vision are variously affected. The movements of the jaw may remain impeded. From a therapeutic point of view recurrence is less to be feared after destruction of the ganglion than after simple resection of the branches. The evidence indicates that complete extirpation should be superior to simple destruction of the ganglion.—*Journal of the American Medical Association*, May 15, 1897.

#### THE CAFFEINE TREATMENT OF HEART DISEASE.

In the *Nord Médical* of May 1 M. G. LEMOINE states that for fifteen years he has given caffeine every day to patients suffering from myocarditis, and he feels certain that this treatment has prolonged their lives by avoiding the various discomforts, attacks of oppression, and temporary asystole to which they had formerly been subject.

M. Lemoine gives an account of a case in which, owing to the permanent and prolonged use of caffeine, the patient enjoyed better health than for many years. The author refers to five similar cases, in the most recent

of which this treatment has been employed for three years. One case was that of an emphysematous subject with cardiac degeneration, in whom this treatment had been instituted seven years ago, and owing to the influence of the caffeine he had been enabled to resume his work.

M. Lemoine states that it is not necessary to employ large doses of caffeine in order to obtain these results; on the contrary he recommends weak doses, and as much as possible doses which vary more or less from day to day. This method has the great advantage of not accustoming the organism to the same dose always; consequently it is possible to continue the use of the drug without increasing the doses.

This method is considered the most logical by M. Lemoine, although he says it may be objected to on the ground of accustoming the organism to a drug and of the physician being obliged to gradually increase the doses until they become excessive. The author thinks, however, that he has answered this objection in presenting the facts themselves of the case referred to. He concludes that the caffeine treatment is indicated in patients who suffer from cardiac weakness due to a disturbance of the pulmonary circulation. He states that he has employed this treatment with admirable results in emphysematous subjects with heart disease.—*New York Medical Journal*, May 29, 1897.

#### THE ACTION OF TAKA-DIASTASE IN VARIOUS GASTRIC DISORDERS.

FRIEDENWALD, of Baltimore, in the *New York Medical Journal* of May 29, 1897, concludes an article on this subject as follows:

1. That Taka-Diastase exerts no influence under normal conditions upon gastric digestion, nor upon cases of nervous dyspepsia with normal motor and secretory functions.

2. That in cases of motor disturbances of the stomach with normal secretory functions, such as atony, Taka-Diastase increases the motor action without in any way influencing the secretory function or the digestion of starches.

3. That in cases of subacidity Taka-Diastase acts differently, according to whether there is a catarrh or a nervous dyspepsia. In nervous cases it has no effect whatever upon digestion, while in cases of catarrh it appears to have a tendency to increase the flow of acid and promote the digestion of starches.

4. That Taka-Diastase exerts its most favorable influence in cases of superacidity. It not only promotes the digestion of starches in these cases, but diminishes the excess of acid and increases the motor function.

5. That Taka-Diastase in a great measure replaces the saliva when this secretion is diminished or absent. It then not only digests the starches in the stomach, but serves the other function of the saliva in stimulating the gastric secretion and therefore promoting the proteid digestion.

#### THE NEW LOCAL ANESTHETIC HOLOCAINE.

HASKET DERBY in the *Boston Medical and Surgical Journal* for June 3, 1897, writes concerning this new substitute for cocaine. He points out that in an article on "Certain Dangers Attending the Use of Atropine," published a few years ago, he called attention to the possible danger of increasing intra-ocular pressure connected with the employment of the ordinary mydriatics. The well known fact that in glaucoma dilatation of the pupil increases and contraction of the pupil diminishes intra-ocular pressure long since led to the observation that the instillation of atropine and allied drugs might produce an attack of glaucoma in an eye predisposed to this disease. This observation was also found to hold good in regard to homatropine and even cocaine. But with the latter agent, used as it so generally is for the purpose of producing local anesthesia, the question of possible ill effects assumes peculiar importance; and, in point of fact, its employment for minor operations on the eye in the case of patients who have arrived at or passed the period of middle age has been seriously hampered by the foregoing consideration.

Other disadvantages are, moreover, found to occasionally attend the instillation of cocaine. General faintness, dizziness, and even vomiting, have from time to time been known to occur. Symptoms of cardiac disturbance, depending no doubt on some peculiar idiosyncrasy, are met with in some individuals.

Search has therefore been made for a local anesthetic that should be free from the disadvantages of cocaine. But none of the preparations experimented with have thus far proved wholly satisfactory. For one of the most recent of these, eucaïne, it has been claimed that no pupillary enlargement, and therefore no increase in intra-ocular pressure,

follows its use. But it causes local irritation, and therefore cannot be employed in inflammatory affections; and its repeated application has been found to finally give rise to pupillary dilatation. It offers no advantages over cocaine, and possesses peculiar drawbacks of its own.

In the January number of his *Centralblatt* Professor Hirschberg announces the receipt of a new local anesthetic, to which he at first gave the name of "amidin." He found its anesthetic effects on the eyeball to be prompt and entire, no local irritation and no pupillary dilatation following its use. He used it with success in the extraction of a traumatic cataract, the presence of which had already given rise to inflammation.

The February number of the same magazine contains a full chemical account of the new substance. Without going into particulars, it is sufficient to say that it is closely allied to phenacetine. It has a powerful local anesthetic action, and is highly poisonous if administered internally, even in minute doses. No local poisonous effect has been noted. It is soluble in boiling water, and should be dissolved in a porcelain vessel, as it causes glass containing an alkali to lose a portion of the latter, which clouds the solution. It has finally been baptized with the name "holocaine." The experiments at Hirschberg's clinic were continued, some forty-five cases having been subjected to its action. Anesthesia came on in from fifteen seconds to a minute, and lasted ten minutes. The instillation of holocaine was accompanied by a slight burning sensation, no greater than that produced by cocaine. The dryness of the corneal epithelium produced by cocaine was here wanting. No pupillary enlargement and no effect on the accommodation were observed.

It was, moreover, found that holocaine could be used in cases where cocaine was either contraindicated or failed to work, as for instance where there existed a considerable inflammation of the conjunctiva bulbi, attended by swelling. Its action was here entirely successful.

The solution of holocaine needs no sterilization, being in the strength of one per cent. itself bactericidal.

Holocaine possesses strongly poisonous properties, acting thus in one-fifth the strength of cocaine. When instilled in the conjunctiva no injurious effects have been observed.

In this new agent, then, we have a remedy that is likely to supplant cocaine in many

cases of ophthalmic surgery. Among its advantages may be reckoned the following:

1. It does not enlarge the pupil.
2. Does not affect the accommodation.
3. Does not increase intra-ocular pressure.
4. Promotes antiseptis.
5. May be used when cocaine is contraindicated.

*Per contra*, its poisonous nature prevents it from being used subcutaneously. And as it does not contract the vessels, operations done under its influence are likely to be attended by more hemorrhage than those performed under cocaine.

Dr. Tauber, who was the first to give an account of the chemistry of holocaine, says that it belongs to the class of ethenylamidins, its proper cognomen being *p*-diethoxythenyldiphenylamidine.

Dr. Derby early obtained some holocaine and at once commenced its use, begging at the same time some of his colleagues to employ it and give him the results of their experience. It had up to the date of his writing (May 26) been used in six operative cases and in ten others. The operations embraced three extractions of senile cataract, one of a dislocated lens, and one discission. Anesthesia was rapid and satisfactory in all these cases, the main contrast with cocaine being the slight flushing of the eyeball. In one case of trachoma, in which Dr. Standish did expression, anesthesia did not come on for over seven minutes, but was then complete. In the ten remaining cases holocaine acted as cocaine would have done, save that there was no effect on the pupil.

Since writing the above an article by Drs. Heinz and Schlosser has appeared in the *Klinische Monatsblätter* for April. They have been working with holocaine for the past four months. The foregoing statements are in the main corroborated. In their experiments one or two drops of a one-per-cent. solution generally brought about entire anesthesia in from forty to fifty seconds. When a second application was made, forty seconds after the first, entire loss of sensation invariably followed in thirty seconds more. The duration of the anesthesia is at least ten minutes. After the opening of the anterior chamber a second application was found to affect both iris and ciliary body, an iridectomy in a case of acute iritis causing no pain. This effect on the iris the author, too, has observed. He had used holocaine in a simple extraction of senile cataract, but finding it impossible to clear the pupil he was obliged to remove

a small piece of the iris after the operation was otherwise completed. No holocaine had been instilled since before the operation; and yet the patient, a nervous and apprehensive woman of seventy-two, suffered absolutely no pain.

In view of all this it would seem that with our present knowledge holocaine is likely to take the place of cocaine in ophthalmic surgery, except in cases where subcutaneous injection is required.

#### THE TREATMENT OF HEMOPTYSIS.

The London *Lancet* of May 1, 1897, summarizes this subject as follows:

The direct effect of drugs in arresting the hemorrhage which occurs in cases of pulmonary tuberculosis is very difficult to estimate with any amount of accuracy. The majority of cases tend to become spontaneously arrested, and any drug which has been given previously is apt to get the credit of stopping the bleeding. Dr. Deguy believes strongly in the value of full doses of gallic acid in this condition, and he gives this drug in doses of from four to fifteen grains in the form of powders, pills, or solutions. In cases where the hemorrhage is very severe he associates the gallic acid with ergotin, thus: Gallic acid 30 grains, ergotin 15 grains; make into twenty pills, of which five or more are to be taken each day. Others, however, do not put much faith in the action of these and other astringents of the same class, and it is difficult to see how such drugs can have any definite action on the bleeding vessels, the walls of which are generally severely diseased. The application of an ice-bag is also another method which is believed by some to be efficacious, while others will have nothing to do with it. It is, again, difficult to see how this method of treatment can be of any direct use except by mechanically assisting to keep the patient quiet. One of the most effective methods of treating an ordinary case of hemoptysis consists in giving a small hypodermic injection of morphine, which generally results in arrest of the hemorrhage, and the patient is at the same time mentally soothed.

#### THE RADICAL CURE OF EPITHELIOMA BY ARSENIOUS ACID.

The operative treatment of cancer has always been felt to be only a *pis aller*, often dangerous in its application, and always uncertain in its results. The fact that it has up

to the present remained the only measure at our disposal is conclusive evidence of the inadequacy of our therapeutical resources. It is not that other methods of treatment have been wanting, but without exception they have failed to fulfil the more or less sanguine anticipations of their discoverers and have consequently fallen into oblivion. Among the numerous remedies recognized in the treatment of cancer at various periods of the history of medicine, arsenic is certainly one of the most ancient. It has been tried internally, and as a local application; but even the temporary improvement occasionally observed by Billroth has not been obtained by other equally trustworthy observers. We are, however, asked by Drs. Czerny and Trunek, of Prague, to reconsider the use of this drug as a topical application in cancerous ulcer; and in an article published in the last number of *La Semaine Médicale* they certainly adduce results which appear to merit our attention. Their first attempts, with arsenic in powder, proved abortive, the thick scab which immediately formed effectually preventing any further action on the diseased tissues. They ultimately decided to make use of a solution of arsenious acid in equal parts of rectified spirit and water, of the strength of one part of the acid in 150 of the menstruum. So far, their observations have borne exclusively on ulcerated superficial growths, the histological structure whereof could be demonstrated by microscopical examination.

The first step is to thoroughly cleanse the sore by vigorously rubbing or scraping the raw surface. The effusion of a moderate quantity of blood is a desideratum, it being indispensable that the remedy should come into contact with the tissues in the presence of freshly exuded blood. The surface of the ulcer is then thoroughly moistened with the solution, shaken up before using, and allowed to dry, preferably without dressing of any kind. Some pain usually follows the application, but not of intolerable severity. A scab forms, over which the solution is applied daily. By and by the margins of the scab tend to separate from the subjacent tissues, and the treatment is continued until the scab is only retained in place by a few loose adhesions. These are divided and the scab removed. A fresh application of the arsenical solution is made, and if on the day following the resulting scab is thin, of a light yellow color, and easily detachable, it indicates that the tissues no longer comprise any trace of

cancerous growth. If, on the other hand, a dark-colored, firm, and closely adherent scab again forms, the whole treatment must be repeated. The thicker the resulting scab the more energetic should be the treatment—that is to say, the stronger should be the solution, the strength of which may then be increased from 1 in 150 to 1 in 100, or even 1 in 80. When the desired result has been attained there remains a granulating wound, covered with a delicate white pellicle, to be dealt with on general principles. The formation of cicatricial tissue may be minimized by the application of boracic-acid ointment along the margins of the ulcerated surface. The duration of the treatment varies from three to four weeks to as many months, according to the depth and extent of the lesion.

The procedure described appears to be especially applicable in cases of cancer of the skin not associated with glandular enlargement, and perhaps also in cancer of the tongue, in which the prognosis is so unfavorable and surgical treatment so unsatisfactory. The authors believe that the effect of the treatment is in part due to the alcohol, and they attach special importance to the presence of fresh blood on the ulcerated surface when making the first application. The remedy is a simple one, and admits of ready trial, and in view of the results which they are enabled to place on record the suggestion will doubtless receive in this country the attention which it appears to merit.—*Medical Press*, May 26, 1897.

#### TREATMENT OF HERPES.

In the *Journal des Praticiens* of June 26, 1897, the following prescription is recommended:

- ℞ Resorcin, 45 grains;  
Cocaine, 15 grains;  
Alcohol, 3 ounces.

This is to be applied by means of a swab to the herpetic spot.

#### THE DOSES OF SOME COMMON DRUGS FOR CHILDREN.

The following dose list of well known remedies is given by the *Journal des Praticiens* of June 19, 1897, for the administration of these drugs to children. First, it is pointed out that the hydrochlorate of quinine is readily absorbed from the skin, provided that it is applied with friction in the following form:

- ℞ Benzoated lard, 6 drachms;  
Hydrochlorate of quinine, 1 drachm.

It is also pointed out that the employment of antipyrin with the hydrochlorate of quinine seems to aid in the solubility and absorption of the quinine, and for this reason the following mixture may be given hypodermically:

- ℞ Basic hydrochlorate of quinine, 30 grains;  
Antipyrin, 15 grains;  
Distilled water, 2½ drachms.

Dissolve by heating, and give 15 minims at a dose.

[It is to be remembered that antipyrin when given hypodermically produces a great deal of pain, although its permanent effect is anesthetic.—ED.]

The dose of salicylate of sodium, which is recommended as an antithermic, analgesic, or antirheumatic, is as follows: For children up to fifteen months, three grains a day; from fifteen months to three years, eight to fifteen grains; from three to five years, fifteen to forty-five grains; from five to ten years, forty-five to sixty grains. [We would consider that these were large doses.—ED.]

In regard to salol it should be remembered that this drug possesses properties very closely allied to those of salicylic acid, and it is therefore a useful intestinal anesthetic. The dose is as follows: Up to fifteen months, one to three grains a day; fifteen months to three years, three to fifteen grains; three to five years, twenty to thirty grains; five to ten years, fifteen to sixty grains.

In regard to the dosage of sulphonal, it is not advisable to administer this drug prior to the third year. From three to five years two to five grains may be given; from five to ten years, five to ten grains may be given. Similar abstentions prior to three years and similar doses after this period hold good in regard to the hypnotic trional.

#### THE MAXIMAL DOSE OF CERTAIN DRUGS BY SUPPOSITORY IN THE TREATMENT OF CHILDREN'S DISEASES.

*La Médecine Moderne* of June 23, 1897, after emphasizing the valuable therapeutic results which are obtained by the administration to children of medicaments in the form of suppositories, proceeds to the consideration of the conditions in which medication by this means is desirable. It is of course to be employed in those instances where the stomach is so delicate that the administration of medicines by the mouth is not possible or is inadvisable, or where the child refuses to swallow the drug. For various reasons it is

evident that the use of suppositories is more advisable in the treatment of children than in the treatment of adults, and while it is entirely true that complete absorption of the drug may be obtained from the rectum, it must also be remembered that absorption is comparatively slow and that full doses must be administered.

In regard to opium it is interesting to note that this journal suggests the employment in suppository in the dose of one-sixtieth of a grain of the powdered drug for each year of the child's age, which may be administered every two hours if the case is urgent. Careful watch must be kept that toxic action is not developed, as evidenced by undoubted sleepiness or myosis, when the drug must be stopped.

In regard to aconite it is an undoubted fact that this drug is exceedingly valuable in the treatment of diseases of childhood, and it is best to give minute doses frequently rather than large doses at longer intervals. One or two drops of the tincture may be given for each year of the child's age, but not more than ten to twelve drops in twenty-four hours should be given for each year. [We consider this a large dose.—ED.]

In regard to belladonna, it is pointed out that this remedy also possesses very valuable properties. It is useful as a sedative for excessive cough, and also is useful to prevent griping. As much as one-sixth of a grain of the extract of belladonna may be given to a child of two years, divided preferably in three or four suppositories.

Digitalis in the form of its powdered leaves is absorbed with difficulty from the rectum. It is best, therefore, to use the tincture, of which four drops may be given for each year of the child's age, divided into two suppositories. [A large dose.—ED.] Larger doses than this should be administered with benzoate of sodium in equal parts, about two grains in each suppository, and two of these suppositories may be given each day.

One of the best ways of employing quinine in the treatment of diseases of childhood is by suppository, and antipyrin may also be given in the dose of from two to six grains in two or three suppositories. It is thought that children have greater resistance to this drug.

In regard to salicylic acid it is also said that the same tolerance exists, it being proper to give eight grains divided into three or four doses. One-sixth of a grain of extract of *nux vomica* may also be given to a child

of six years, divided in three suppositories; but it is best not to employ strychnine until the child has reached ten years.

A special recommendation of the use of iodine by the rectum is made; three to four grains for each year of the child may be placed in two suppositories, but half a grain is sufficient each day if the medicine is to be administered for a considerable period of time. [We would fear rectal irritation.—ED.]

The bromides may also be given in suppository.

#### *BLUE PYOKTANIN IN THE TREATMENT OF INOPERABLE MALIGNANT GROWTHS.*

In the *Journal of the American Medical Association* of June 26, 1897, SLACH describes his use of pyoktanin in the treatment of tumors, and adds a word as to the technique of the treatment, which varies with the location. The injection should be made under strict aseptic and antiseptic precautions. The skin where the needle is to enter should be thoroughly cleansed with bichloride solution. The needles may be long, short, or curved, but must not be of too small caliber, and should be boiled after using.

The author used the large hypodermic syringe and injected from one to two cubic centimeters of a two-per-cent. solution. This is more than twice as strong as recommended by Drs. Meyer and von Mosetig. The patient is given the pyoktanin pencil, one-per-cent. solution, or a two-per-cent. powder, as the case may require, to apply daily.

Thus far he has seen no untoward effects from its use. The only objection to it is that it stains everything with which it comes in contact, but what is the soiling of linen when compared with the following advantages: (1) Its analgesic effects are marked, as patients soon rest easily without the aid of morphine; (2) "the improvement of the function of the part involved"—the man who could hardly speak so as to be understood talked without difficulty after the third injection; (3) the improvement in general health which has taken place in all five of the writer's cases; (4) the element of hope that is added to the life of suffering man, brightening the remainder of his sojourn.

While he does not claim to have cured his patients, still he has relieved their pain and rendered them less burdensome to themselves and their friends. He agrees with Dr. Meyer in von Mosetig's conclusions, "that it has been proved by practise that parenchyma-

tous injections of inoperable malignant growths with pyoktanin can produce disappearance of malignant tissue, though in exceptional cases, and can heal neoplastic ulcerations."

Pyoktanin, when properly used, is certainly a palliative treatment for cancer that deserves an honest, hopeful trial, for by its use many have been relieved and some cured.

#### DIURETIC ACTION OF SALICYLIC ACID AND CAFFEINE.

SIEGERT (*Münchener Medicinische Wochenschrift*, May 25, 1897) concludes a study of this subject. In a case of chronic peritonitis salicylate of sodium in both small and large doses lessened diuresis, the specific gravity of the urine being increased. With pure caffeine there was constantly observed a markedly increased diuresis, but with caffeine sodium salicylate (diuretin) the opposite effect was seen, the caffeine diuresis being suppressed by the salicylate. Caffeine produced its most marked effect after a course of small doses of salicylates. The use of caffeine alone made tapping of the ascites unnecessary, owing to the absorption of all the edema, which, on the other hand, was increased by the use of salicylates. The author shows by experiments on animals how the salicylates can abolish the diuresis produced by caffeine. Thus it is undesirable to use the combination of caffeine and salicylates where a diuretic effect is aimed at. In one case where tapping had been done some ninety times, the use of caffeine made any further tapping unnecessary. The author has used caffeine with digitalis, and has found the diuretic effect very marked. It is desirable to use the insoluble caffeine in preference to the soluble combinations. The author would recommend the use of caffeine with or without digitalis in all cases of venous engorgement with intact kidneys in order to remove the edema by diuresis.—*British Medical Journal*, June 26, 1897.

#### A PLEA FOR VENESECTION.

In quite a long article on this subject in the *Australian Medical Gazette* of May 20, 1897, HAYWARD discusses his experience with venesection, and in conclusion states that the class of cases in which he recommends blood-letting may be summed up as those in which, from any cause, there is cardiac insufficiency and toxemia present in such a

degree as to endanger life. It is only in such cases that he has practised it, and consequently he does not feel justified in strongly recommending it in other instances. He believes, however, that the range of cases might be judiciously extended. For instance, in certain cases of acute pneumonia—those in which the fever is high and the delirium intense—it is not the lesion in the lung that gives rise to these symptoms; it is the acute toxemia, which has the effect of completely upsetting the nervous system, and inducing paralysis of the cardiac muscle. He believes that the withdrawal of a fair quantity of this poison-laden fluid would be fraught with great benefit. The writer is well aware that pneumonia was the stage on which the venesectioners and antivenesectioners fought fifty years ago, and victory was claimed by the latter inasmuch as their results were at least as good as those of their opponents, thereby proving at any rate that there was no necessity to resort to venesection. But a very palpable fallacy existed in this contention. All the cases of pneumonia were bled as a matter of routine by the advocates of blood-letting. The writer contends that the practice is only suitable in a certain type of the disease—the minority of cases—and that it would be decidedly wrong to adopt it in the remainder.

In certain cases of typhoid fever the writer believes we might bleed with advantage, but owing to the prolonged duration of the disease a very careful selection of those suitable would have to be made. He is fortified in this view by clinical experience. We must all have noticed how, when the headache has been intense, relief has followed a more or less extensive epistaxis, and a patient often improves after the occurrence of a moderate hemorrhage from the bowels. Very recently the author had a case in which no subsequent rise of temperature took place after such a hemorrhage, the patient rapidly improving. The trouble in these cases is that the hemorrhage is far from being moderate, and is too often repeated. The writer does not look upon these incidents as an example of the *vis medicatrix naturæ*, and therefore pointing to the treatment that should be adopted; he considers them as purely accidental, but none the less an indication of what result might be anticipated if the bleeding was due to artificial and not to natural causes.

Are we not too much afraid of the after-effects of bleeding? Is it not an almost every-day matter of wonder to us how pa-

tients recover after severe hemorrhage? Last year the writer had a patient, a gentleman over 80 years of age, who had a severe attack of epistaxis. He had lost a quart of blood before the author saw him and plugged the nostrils. In less than a week he had completely recovered from the loss, and was at least as well as he was before the occurrence.

In conclusion the writer says that although he has given expression to his own thoughts, and has endeavored to bring before the reader the conclusions he has formed from his own experience, he does not wish to be understood as having given anything novel. Doubtless venesection has most undeservedly gone too completely out of practise. If we use it with just discrimination, if we are guided by scientific principles in our use of it, if we do not follow in the footsteps of our ancestors and regard it as an empirical procedure, to be adopted in and out of season, he thinks that we shall have at our command an agent that, though terribly abused in the past, has been, and may be, instrumental in alleviating suffering and in averting death.

#### THE CUTANEOUS ABSORPTION OF IODINE.

LINOSSIER and LANNOIS (*Bulletin de l'Académie de Médecine*, No. 17, 1897) refer to the fact that if the healthy skin is painted with tincture of iodine a small quantity of the halogen is found constantly in the urine, and they have experimented as to the conditions under which this absorption takes place. They find that (1) tincture of iodine is absorbed by the skin in very small and inconstant quantities if the painted surface is freely exposed to the air; (2) if the surface is covered hermetically the quantity absorbed is much greater, in one case the amount recovered from the urine being nearly a third of that applied to the skin; (3) the greater absorption from the covered surface proves that the iodine enters chiefly by the skin itself, and not by the inhalation of its vapor; (4) the superficial alteration of the epidermis caused by the tincture, unless it has progressed to the destruction of the corneal layer, seems to act rather as an obstacle to absorption than otherwise, since it is during the first few hours after its application that the urine is richest in iodine, while the disorganization of the skin proceeds slowly; (5) iodine is also absorbed from iodized cotton-wool applied to the skin; (6) even under the

most favorable conditions this absorption is too inconstant in amount to be used as a general means of administering iodine; (7) iodoform and iodide of ethyl are absorbed by the healthy skin, the latter in such quantity as to be available, if necessary, for introducing iodine into the system.—*British Medical Journal*, June 26, 1897.

#### THE ACTION OF IODIDE OF POTASSIUM ON THE BLOOD OF SYPHILITICS.

COLOMBINI and GERULLI, working at the Dermato-syphilitic Institute in Sienna, find that iodide of potassium given by the stomach before any other drug, and in the early stages of syphilitic infection, causes an increase in the number of red corpuscles and the quantity of hemoglobin. If the administration is continued, sometimes a diminution of the red corpuscles, followed by a progressive and continuous increase, occurs; sometimes the increase is continuous and not interrupted by a decrease. When the iodide is stopped the red corpuscles and hemoglobin tend at first to diminish, but afterwards start afresh to increase. At the same time there is a notable and constant increase in body weight. The authors attribute the beneficial results of treatment to a specific action of the iodide upon the syphilitic virus. They believe that iodide of potassium in moderate doses, and over a moderate time, is the best remedy for the severe forms of chloro-anemia due to syphilis. A parallel series of experiments on the blood of healthy subjects showed that under iodide of potassium there was constant diminution of hemoglobin and of red corpuscles. The white corpuscles appeared unaffected. The body weight decreased, especially when the dose of iodide of potassium was progressively increased.—*British Medical Journal*, June 26, 1897.

#### FOUR SUCCESSFUL CASES OF TRANSFUSION OF SALINE FLUID.

*Apropos* of the numerous articles recently published in the *GAZETTE* concerning this means of treatment, the following facts named by RAW in a brief report in the London *Lancet* are of interest. He thinks there can be no doubt that we have in transfusion one of the most simple yet efficacious remedies in all cases of shock from hemorrhage. How far it is of service in cases of nervous shock and collapse is yet undecided, but in some cases it is of great

value. Larger quantities should be given than those generally recommended, four or five pints being a usual quantity. The writer has given as much as twenty-four pints at four injections within twenty-four hours without any apparent discomfort. He has noticed in several cases the occurrence of a rigor, commencing from half an hour to an hour after the operation and lasting about five minutes, with a high temperature. This seems to have no serious effect, the temperature quickly subsides, and recovery is not retarded by it. In a case reported by the author he says he has every reason to suppose that an acute attack of septic osteomyelitis was cut short by the transfusion, his explanation being that an increased volume in the vessels would offer a greater resistance to attack and at the same time dilute the blood-stream and so disperse the micro-organisms. If this be so, there is every reason to suppose that transfusion may be employed in acute specific diseases due to micro-organisms, as in any case it could have no other than a highly beneficial effect if performed with ordinary care and with a sterilized solution. The apparatus he uses consists of an ordinary glass funnel and tubing, with a glass nozzle for insertion into the vein.

#### TRACHEAL INJECTIONS IN THE TREATMENT OF LARYNGEAL AND PULMONARY INFLAMMATIONS.

J. A. THOMPSON writes to the *Journal of the American Medical Association* of June 26, 1897, on this rather heroic plan of treatment. He points out that there are several reasons for the slow growth of this manner of treatment in professional favor. The principal one is that few physicians are sufficiently expert in the examination and treatment of the upper air passages to employ it. As a rule they consider all lesions of the nose and throat as local, with but little influence on the health of the patient. This lack of appreciation of the importance of these conditions is largely responsible for the neglect of direct medication. Another reason for the limited use of intratracheal injections is the mistaken opinion that they are necessarily painful and irritating. Our ideas of the sensibility of the tracheal and bronchial mucous membrane have been erroneously deduced from that of the larynx. Below the glottis the nerves of sensation are few, and the membrane is not irritated by solutions much stronger than those we use in the

larynx. While these reasons have been potent in preventing the more general knowledge and use of this method, there are other and much better reasons for the general use of direct medication in inflammatory diseases of the larynx, trachea, bronchi, and lungs.

By the method of intratracheal injection we get the direct local action of the medicines on the diseased areas. In bronchiectasis no medicine given by the mouth will prevent the decomposition of the secretions in the dilated bronchi. The odor and the absorption of septic material from them cannot be controlled. A few tracheal injections will usually disinfect the cavities so that the odor disappears and the temperature becomes normal.

It is possible by intratracheal medication to produce a rapid and prolonged general effect. Anesthesia gives daily and hourly evidence of the rapidity with which volatile medicines are absorbed through the lungs, and their effect on the whole organism. From three to five minutes is a sufficient time for an expert to obtain chloroform anesthesia. You can produce as rapid an effect, and one much more durable, by injecting into the trachea medicines which volatilize slowly at the temperature of the body. Where a dose of menthol has been given in this way you will find the surface flushed in five minutes, the cold extremities have become warm, and sometimes the patient breaks out in a profuse perspiration. This stimulating action lasts for hours.

Medicines used by tracheal injections are not changed into unknown compounds by passing through the digestive organs. For this reason we can be more certain of their action. No one would think of treating a tubercular laryngitis by internal medication alone. There is just as much reason for applying medicines of known beneficial local action directly to the lungs as there is for using them in the larynx.

Where medicines are injected directly into the trachea they have no deleterious effect on the organs of digestion. Our valuable expectorants, such as are used in acute and subacute catarrhal diseases, act injuriously on the stomach and intestines. The name of one class, "nauseating expectorants," testifies to the universal recognition of this fact. The cure of a bronchitis by direct medication without interfering with nutrition is an advance in therapeutics.

Direct antisepsis can be secured by local medication. It is not possible to obtain this

result by remedies given internally. We are prone to forget that in tuberculosis we are dealing with a mixed infection. In the stage of ulceration and breaking down of tissue infiltrated by tubercular matter there is always a secondary infection by the germs of sup-puration. It is to these, in all probability, that most of the fever, the night sweats, and the other evidences of sepsis are due. We do not attempt to disinfect a leg ulcer by medicating the stomach. It would be just as rational to do so as it is to attempt to disinfect suppurating cavities in the lung by medicine administered per os. In cases where tracheal injections can be tolerated the anti-septic action of the remedies chosen will be very speedily shown by the subsidence of the cough, by change in the character of the expectoration, and by the decline in the fever.

The administration of medicines by intra-tracheal injections does not interfere with any other line of treatment. Diseases in other organs may be treated or tonics given, while local treatment of the lungs is being used, without any incompatibility. Where medicines are given by the tracheal rather than by the esophageal route we can relieve symptoms in hopeless cases without narcotics. We thus avoid their bad effects on nutrition. We also escape their secondary depressing action on the nervous system. A little menthol injected into the trachea will quiet a cough longer and more effectually than will a quarter of a grain of morphine given hypodermically.

Conditions not affected by constitutional medication can be cured by tracheal injections. Gummata in the lung, which resisted all other treatment, have been cured quickly and easily by direct medication of the suppurating cavities.

There are several conditions necessary for success in this method of treatment. The first essential is that the doctor himself be skilled enough in laryngology to do the work rapidly and delicately. The patient must possess a reasonable amount of self-control and be willing to follow directions implicitly.

It is probable that the medicines used for this treatment should be such as volatilize slowly at the temperature of the body. They should be soluble in the vehicle employed. The solutions used should not be too irritating. The most serviceable solutions are menthol, two-per-cent.; guaiacol, one-per-cent.; creosote, one-per-cent.; camphor, two-to three-per-cent. Any of these may be combined. In acute diseases the menthol

and camphor solutions are most efficient. In tuberculosis menthol and guaiacol give the greatest relief. Guaiacol gives good results in any septic condition in the lungs or bronchi. The vehicle used should be one of the light petroleum oils or olive oil. Alcohol and water are too irritating and produce violent coughing. There is ordinarily no spasm and but little cough or distress after an injection of the above solutions. The dose is from one to four drachms.

---

#### *SOME POINTS IN THE TREATMENT OF SYPHILIS.*

In *Treatment* of May 27, 1897, C. F. MARSHALL tells us that the following observations deal with a few practical points which have occurred to the author during the treatment of a considerable number of cases of syphilis:

The primary sores of syphilis are of such a variable nature that it is often impossible to say whether a given sore will be followed by secondary syphilis or not, and consequently surgeons are divided in opinion as to how far such sores should be treated by mercury, some even going so far as to omit mercury altogether in the primary stage, and to wait for secondary manifestations to confirm the diagnosis.

Many apparently "soft sores" are followed by secondary syphilis, especially in females, among whom the typical indurated chancre is much less common than in males. Again, a soft sore appearing a few days after connection may, after a few weeks, become indurated owing to double inoculation. Enlargement of the glands in the groin helps us in diagnosis to a considerable extent, but must be regarded with caution. Distinctly hard and enlarged glands combined with much induration of the primary sore are of course almost diagnostic, but the so-called "shotty glands" are very deceptive, and may be felt in many persons after herpes prepu-cialis, or simple inflammation of the smegma glands of the penis; and in fact in some people without a sore at all.

The general rule for treatment he thinks should be not to treat any primary sore (in the absence of secondary manifestations) with mercury, unless it is a typically indurated sore with hard and enlarged glands in the groin. All other sores are doubtful, and it is better to wait for secondary events to occur before submitting the patient to a course of mercury. If mercury is given at once in such cases the diagnosis is still fur-

ther postponed, and even perhaps never cleared up till several months later; for we know that mercury delays the secondary symptoms, and in some cases makes them so mild in character that, unless the patient is examined several times a week, they may not be observed at all.

It may be urged that by adhering to this rule a certain amount of time will be lost in treatment in many cases. No doubt this is the case, but the writer thinks, it is better to make certain of the diagnosis than to try to save time by putting doubtful cases on a course of mercury. In any case the time lost is only a few weeks as a rule.

The two best forms of treatment during active secondary syphilis (and this applies also to primary cases where the diagnosis is certain) are: (1) intramuscular injections, and (2) inunction.

The best form of mercury to use is the double chloride of mercury and ammonia (sal-alembroth). Ten minims of this (containing one-third of a grain of perchloride of mercury) is injected into the gluteus maximus once a week, by means of a platinum-iridium needle. This method has the advantages of exact dosage, cleanliness, secrecy, and of personal administration by the surgeon himself. The only disadvantages are pain, which varies in different subjects, and sometimes induration of the buttocks at the points of puncture.

This, although an old method of treatment, is still one of the best, especially in cases such as iritis, where rapid mercurialization is required. The best preparation to use for inunction is the unguentum hydrarg. cinereum (hydrarg. 1 part, lanolin 1 part, olive oil  $\frac{1}{2}$  part). About half a drachm of this is rubbed daily into the skin. The rubbing should be continued for twenty minutes at a time, and different parts of the body used alternately. A warm bath should be taken before each inunction.

With either of these methods the symptoms usually disappear in from four to six weeks. Sometimes, however, cases are severe, and resist either or both forms of treatment combined. In such cases the biniodide of mercury and potassium often does much good, and in cases which resisted all such treatment the author has found much benefit from the double iodide of mercury and arsenic (Donovan's solution).

Whichever treatment is used, whether inunction or injection, it should be continued till all symptoms have disappeared. After

this it is sufficient for the patient to take mercury in the form of pills, either a grain of hydrarg. cum creta ter die, or two grains of pil. hydrarg. bis die, combined with one-eighth to one-fourth of a grain of opium. These should be continued for a further period of twelve to eighteen months, gradually reducing the frequency of the dose.

The well known dusting powder of calomel and zinc oxide is very useful for drying up condylomata, but the writer has had better results from naphthol (two to four drachms to one ounce of zinc oxide).

Naphthol in this form is especially useful in ulcerating condylomata, and also in the treatment of primary ulcerating sores, hard or soft.

Chromic acid (twenty grains to one ounce) appears to be the best application to ulcers of the buccal cavity and also to fissures of the lips. If, however, there is extensive sloughing ulceration of the tonsils and fauces, he has found chlorine by far the best application. A solution of nascent chlorine is obtained by acting on ten grains of chlorate of potash with a drachm of strong hydrochloric acid, and dissolving the gas in a pint of water. This is an old remedy for diphtheritic throats, but he has not known it used before in syphilis. It may be used as a gargle or it may be applied on a sponge.

We are all familiar with anemia occurring in syphilitic patients. However, it has been shown by Justus, of Budapest, that not only is there a diminution in the amount of hemoglobin in syphilis to a greater or less extent, but that there is a further diminution immediately after the administration of mercury; altogether after continuance of mercurial treatment the amount of hemoglobin ultimately reaches a higher level than that observed before treatment was commenced.

The anemia thus produced is sometimes severe, and requires treatment in itself. In such cases the writer has found arsenic of more value than iron, either alone or combined with mercury as Donovan's solution. The chief value of the latter drug would seem to lie in the power of the arsenic contained in it counteracting the tendency of the mercury to lower the hemoglobin in the blood.

There are certain points in the local treatment of tertiary sores which it is worth while to consider. It is true that the majority of syphilitic ulcers will heal under iodides with "ordinary dressings," but much time may be gained with more energetic local treatment

than that usually employed; even mercurial ointments and lotions may be much improved upon.

The best treatment for all tertiary and rupial ulcers is a two-per-cent. ointment of iodine made with lanolin and vaselin. Under this treatment the sores rapidly become clean and heal by healthy level granulation in much less time than cases treated in any other way, so far as discernible.

Sloughing ulceration of the throat is best treated with the chlorine lotion recommended for secondary ulceration.

#### A RESEARCH UPON SARSAPARILLA.

In the *Medical Chronicle* for May, 1897, LEECH gives a summary of the results obtained by Schulz in the Pharmacological Institute of Dorpat by a study of this drug. These researches by Schulz on the composition of sarsaparilla were made prior to 1892 under the direction of Professor Kobert, who has already set forth the general results obtained in the *Deutsche Medicinische Wochenschrift* of June 30, 1892. In the present paper the full details of the research are given, together with an account of the history and botany of sarsaparilla.

Opinions as to the value of this drug as a therapeutic agent have always differed widely. Even when it was most largely used there were many who, on the ground of experience, denied its potency, and now that it is relegated for the most part to popular or domestic medicine there are still some who hold, also on the ground of experience, that it has a curative influence in certain forms of disease.

It is manifest that if sarsaparilla has such an influence it must depend on some active substance the root contains, and Schulz's investigations have been made for the purpose of obtaining further information as to the nature of the active principle or principles.

As early as 1824 Pallota, of Naples, separated from sarsaparilla a substance, parillin, which was subsequently obtained in a pure state by Flückiger, who gave as its formula  $C_{40}H_{70}O_{18}$ , or  $C_{40}H_{68}O_{18}$ . This substance has also been called by some smilacin. Otten, in 1876, separated another substance, which Merck has since prepared commercially, viz., sarsaparillasaponin. To this substance the names of smilacin and sarsasmilacin have also been given. A third substance, sarsasaponin, has been obtained by Schulz.

These three compounds are supposed to

belong to a group of saponin substances, and differ in physical properties and pharmacological powers. Parillin is a crystalline substance insoluble in cold water. It is soluble in absolute alcohol, but in alcohol diluted with water it becomes less soluble as the amount of water is increased. Sarsasaponin is also a crystalline substance, but it is soluble in water. It dissolves only to a slight extent in absolute alcohol. In diluted alcohol it becomes more soluble as the amount of water is increased. Smilacin is soluble in water. As prepared by Merck for commerce it is amorphous, but it is capable of crystallization.

All three substances are glucosides, and when boiled with dilute acid yield glucose and a new compound, which, in the case of parillin, is called parigenin. The other two substances yield sarsasapogenin.

Schulz gives a long account of the reactions yielded by parillin and sarsasaponin, which are, however, only of chemical interest.

The pharmacological effects of parillin, smilacin, and sarsasaponin resemble generally those produced by the active principles of quillaia bark (quillagic acid and sapotoxin), but they are less toxic. Of the three parillin is the least powerful, sarsasaponin the most so. When taken by the mouth they cause salivation, nausea, irritation of the throat, vomiting, and diarrhea. Injected under the skin they cause abscess; introduced into the blood they tend to destroy the red corpuscles, and cause death after the lapse of several hours. They are not absorbed from the healthy stomach, nor when injected subcutaneously. They are excreted when intravenously injected by the intestinal mucous membrane, stomach, and kidneys; and Schulz says by the salivary glands also, but he gives no proof of this assertion. Like other saponin substances they powerfully influence muscle tissue when directly applied to it, causing contraction, rigidity, and loss of contractility. The motor nerve and endings seem to be killed earlier than the muscle. When circulated through the isolated heart of a frog they cause contraction of the muscle tissue, and limit the heart movements. They therefore decrease the volume of fluid expelled by each cardiac contraction, an effect which is the reverse of that produced by digitalis. Eventually the heart's movements cease, but if fluid which contains no poison be subsequently circulated through the heart, it recovers. If added to blood outside the

body, they have a powerful influence, causing solution of the red corpuscles. They are in this respect more active than many more toxic saponin-like substances, and it is worthy of remark that though parillin is distinctly the weakest in its general toxic effects and in its power of influencing the tissues, whilst sarsasaponin is the strongest, yet in its action on the blood parillin is almost as powerful as sarsasaponin, and distinctly more powerful than smilacin. Because of this action on the blood, all these substances cause hemoglobinuria and methemoglobinuria; eventually bilirubin appears in the urine. Owing to its effect on the blood, the subcutaneous and other tissues after death have often a yellowish aspect, and the exudations in the cavities are of a reddish color. In warm-blooded animals the intravenous injection of doses which eventually cause death leads to but little change in the blood-pressure or frequency of the heart's beat.

The three active constituents of sarsaparilla produce their most powerful effect on the intestinal canal, causing increased peristalsis and injection, sometimes inflammation of the large and small intestine, the contents of which (post mortem) are found to contain bloody mucus. Ulceration of the stomach and intestines is sometimes present. The urine usually contains blood-coloring matter when an animal is poisoned by the intravenous injection of parillin, smilacin, or sarsasaponin, and the kidneys are found (post-mortem) of a dark-red color, the tubules containing red-colored contents.

It is manifest that the pharmacological effects of the active principles which have been separated from sarsaparilla throw no light on its supposed curative influence on syphilis and other ailments. It is possible, indeed, that the increase in the flow of saliva which the saponin constituents tend to produce may have some beneficial effect in lesions connected with the mouth and throat; perhaps, too, the large quantities of fluid which were at one time taken with sarsaparilla preparations had a beneficial effect. But Schulz's researches strengthen the views entertained by the majority of physicians that sarsaparilla as a therapeutic agent has no important value. It has no ill effects because its active principles are not absorbed. Does it contain any other active principle which has not yet been discovered? The care with which the chemical examinations have been conducted by Schulz and other observers renders this improbable. Pereira, indeed, found in it an

essential oil, but as 140 pounds only yielded a few drops it is hardly likely that this constituent gives efficacy to the drug.

#### NOTE ON THE STATISTICS OF CARBOLIC ACID POISONING.

We have already called attention in the editorial columns of the THERAPEUTIC GAZETTE to the results of the studies of Dr. MANN on this subject. In the *Medical Chronicle* for May, 1897, he publishes additional facts, as follows:

In a paper on the statistics of carbolic acid poisoning, contained in the December number of the *Medical Chronicle* for 1896, it is stated that the number of suicidal deaths due to carbolic acid in 1895 could "probably show a geometrical augmentation corresponding in magnitude with that of the preceding year." At the time that this statement was made the annual report of the Registrar-General for 1895 had not yet appeared; it has since been published, and amply corroborates the above quoted forecast. In 1893, 117 persons (60 males and 57 females) poisoned themselves with carbolic acid; in 1894 the number had increased to 167 (82 males and 85 females); and in 1895 the total reaches 224 (114 males and 110 females). In the paper, which deals with the statistics of the decennium 1885 to 1894, it is stated that carbolic acid stands first in the list of poisons selected by women who committed suicide during that period, and that it ranks second as a suicidal poison among men; in the decennium 1886-1895 it heads the list of suicidal poisons with men, as well as with women. Since 1890, when the total number of suicides due to carbolic acid was forty-three, the number of deaths thus caused has increased year by year, until at the end of five years it is augmented more than five-fold. In the year 1895, 347 males committed suicide by poisoning; of these 114 resorted to carbolic acid, leaving 233 to be apportioned among the twenty-five remaining poisons which were used, apart from a number of suicides by poison in which the kind of poison is not specified. In the same year 233 females committed suicide by poison; of these 110 resorted to carbolic acid, leaving only 123 for the twenty-one remaining poisons which were used; again apart from a number not specified. It will thus be seen that one-third of the males and very nearly one-half of the females who poisoned themselves in 1895 did so with carbolic acid.

These figures speak eloquently in favor of some restriction in the sale of carbolic acid to the general public. Surely the time has come when a poison which accounts for 224 suicidal deaths out of a total of 580 caused by poison in one year—a proportion coming within measurable distance of one-half—should be placed out of reach of those who probably for the most part only for the moment estimate the value of life so cheaply as to throw it away in a fit of anger or of maudlin intoxication. It is not the writer's purpose again to go over the grounds for believing that, although restriction in the sale of carbolic acid would not save the equivalent of every life which is taken by that poison under the present state of the law, it undoubtedly would save a very large proportion of lives thus lost. When consideration is bestowed on the fact that in 1895 the number of suicidal deaths from opium—the poison which stands next highest to carbolic acid as a suicidal poison—amounted to only sixty-eight, carbolic acid accounting for 224, it must be allowed, for reasons previously given, that facility of access to a poison is a direct incentive to the suicidal act.

#### OCCLUSIVE DRESSING WITH AIROL PASTE.

P. BURNS, of Tübingen, recommends his airol paste in the highest terms as an ideal dressing for sutured wounds. It dries rapidly and sticks closely, is powerfully antiseptic, and absolutely unirritating to the most sensitive skin; but its chief advantage is that it allows the secretions to ooze through it. He has been using it for six months, especially after laparotomies, herniotomies, and ignipunctures, and has not had a single stitch-hole suppuration with it. He concludes with the statement that occlusion with airol paste insures in the simplest manner a flawless *prima intentio*. His formula is: Airol, mucil. gummi arab., glycerin, of each 10 parts; bolus albus, 20 parts. He uses it even in wounds with drainage.—*Journal of the American Medical Association*, July 3, 1897.

#### TREATMENT OF PROSTATIC RETENTION.

ENGLISCH (*Wiener Klinik*, April, 1897) gives elaborate instructions with many useful hints of practical import on the treatment of urinary retention, both acute and chronic, due to hypertrophy of the prostate. Whilst

advocating catheterism as a valuable and almost exclusive method in a large majority of cases of prostatic diseases, he points out the probable danger of such treatment and insists strongly on the necessity of avoiding as far as possible irritation and septic infection of the bladder and urethra during the use of instruments. Advanced prostatic disease is often associated with inflammatory conditions of the bladder and kidneys, and occasionally with uremia. In cases of recent retention in which the urine is secreted in full quantity, and in an apparently healthy condition, there may be a predisposition to urethral fever and other results from catheterism in consequence of: (1) Anomalies of renal secretion, especially diminished or increased secretion of urea, oxaluria, and diabetes; (2) tuberculosis; (3) altered condition of the blood, such, for instance, as occurs with malarial fevers; (4) impaired innervation; (5) alcoholism.

Before the first use of the catheter an attempt should be made to submit the urine to chemical examination. The author is in favor of the soft rubber catheter. In cases in which this cannot be passed he would use Mercier's catheter with either a single or double bend near the extremity, or the ordinary gum elastic catheters stiffened and suitably curved on wire stylets. In relieving the overdistended bladder the author lays great stress on gradual and interrupted removal of the urine. He lays it down as a rule that the longer the retention has lasted the slower should be the process of emptying the bladder. He would at first withdraw from 200 to 250 cubic centimeters of urine, and then inject about half this quantity of boric solution, and continue this procedure, which it is stated may take from twelve to twenty-four hours, until the bladder is completely emptied.

In many cases of prostatic retention, and especially in those in which the bladder is more or less paralyzed, the author would pass a soft catheter, and allow it to remain for several days. Such practise, which should be associated with frequent injections into the bladder and urethra with the view of preventing or removing symptoms of septic irritation, is held to be indicated (a) when the passage of a catheter is either very difficult or causes much pain, or is followed by urethral fever; (b) when the condition of the urine necessitates frequent injection of the bladder; (c) when the relief of the retention is followed by very frequent micturition; (d) when false passages exist; and (e) when frequent visits of the surgeon to a private

patient in the course of the day are very inconvenient, or impossible. With careful and frequent injections a soft rubber catheter may be retained from one to three weeks without causing any serious irritation of the bladder and urethra or incrustation of the instrument. It is acknowledged, however, that in many cases catheterism fails or does mischief, and it becomes necessary to have recourse to a cutting operation. Suprapubic cystotomy performed with the object of establishing a fistula or removing the enlarged prostate, and also perineal prostatictomy, are regarded as failures. On the other hand, ligature of the vasa deferentia and double castration have been followed by good results.—*British Medical Journal*, July 3, 1897.

#### BONE TRANSPLANTATION AS A SUBSTITUTE FOR AMPUTATION.

BARDEN-HAUER (*Revue de Chirurgie*, January, 1897) has lately resorted to division and transplantation of one-half of a healthy metatarsal bone for disease and death of an adjacent bone shaft. In cases of the partial or complete destruction of one of the metacarpal or metatarsal bones, by this method he has had in several instances the most gratifying results. Twice he applied this device to exterior destruction of the lower end of the radius. He has also executed a remarkably ingenious operation for the restitution of the upper end of the humerus, by detaching the spine of the scapula from its muscular attachments, cleaving through the ridge close to its base and freeing it on either end. He then transported this segment of live bone into the gap left by the removal of the destroyed shaft. The result, as in his other cases, was successful. In young subjects the scapular spine is reproduced, care being taken to always leave the periosteal investment behind.—*Journal of the American Medical Association*, May 15, 1897.

#### ANOTHER METHOD OF AMELIORATING BY OPERATION OTHERWISE INCURABLE INCONTINENCE OF URINE.

WILLIAM ALEXANDER (*The Lancet*, July 3, 1897) presents the following clinical history, which is of interest because of the treatment he devised:

Two years ago, on April 30, 1895, a woman aged thirty-four years came into the Royal Southern Hospital suffering from incontinence

of urine that had existed for the past fourteen years. She had always been delicate (tuberculous), and fourteen years ago she had diseased bone removed from the sacrum. It was after this operation that her urinary troubles began. At first she could not pass urine, then it began to dribble away, and she could not retain it for any length of time; and soon it flowed away constantly except when she was asleep, and then she would keep fairly dry for short periods. Examination on admission showed that she had no control over the rectum or urethra, the sphincters were quite flaccid, and the mucous membrane everted and congested. The uterus dropped down, and the lower part of the vaginal walls was everted. The whole vulva and perineum were congested, excoriated, and covered with salts and mucus that adhered to the hairs and skin, and the whole region looked, smelt, and felt very unpleasant. The idea of diverting the urine from the imperfect vesical reservoir into a rectal one, as had been done in previous cases, was not applicable here, as the rectal sphincter was paralyzed, and would not hold water. The author could find no reference to such a case in the manuals of surgery or in monographs on urinary diseases, and it was only after much thought that he determined to close the urethral opening, and make a permanent suprapubic opening as high as possible and to which an appliance could be fixed that would carry off the urine.

The formation of a suprapubic opening did not present any difficulties, as the bladder could be pushed up into the wound by the aid of a catheter. The bladder-wall was stitched to the wound in the skin, and the wound allowed to heal before the urethra was closed. The closure of the urethra is apparently a simple operation, but in practise the author found it very difficult. Suprapubic drainage is very imperfect. The tube in the bladder becomes surrounded by mucous membrane and is practically closed, whilst the urine issues by the side of the tube, and, worst of all, the forces of Nature tend to send the stream by the old channel, the urethra. Hence union of the plastic wound to close the urethra is not always or often sound along the whole line of the suture the first time, and several operations were required in this case before closure was complete.

Experience suggests the following directions to the operator who wishes to close the urethra: First, insert a thin elastic ring pes-

sary into the bladder through the suprapubic opening, which, when it expands, is to lie in the fundus vesicæ, with part of its circumference over the inner orifice of the urethra. This ring keeps the bladder from contracting, converts it into a pool that can be drained by a siphon, stops the natural tendency that exists to force the urine into the urethra, and blocks that opening. This extraordinary procedure was of great value, and the author would certainly adopt it again. Its insertion, retention, and removal did not present any difficulties or inconveniences, although theoretically it should have produced both. The urethra is best closed by splitting the mucous and muscular coats, turning the former in toward the bladder, and stitching together its raw and now external surfaces with numerous fine catgut sutures. The raw surfaces of the muscular coat are simply brought together by fine silkworm-gut sutures. The method of drainage is simplicity itself. It consists in the ivory nozzle of a Higginson's syringe, with the curves of the neck and body of the nozzle exaggerated so as to have the shoulder below the neck more pronounced. A rubber tube with a tap at the end that can be brought through the dress and so allow the bladder to be emptied with more than usual facility completes the apparatus. It is really self-retaining, but a bandage around the body prevents the ejection of the tube under any great strain or awkward twist of the body. When the tap is closed the urine, collecting, distends the bladder and the tube, and as these become distended the internal hydraulic pressure keeps the shoulder of the nozzle applied to the inner margin of the opening until the patient feels the distention and lets the water flow away. Dr. J. A. Craig and the author were planning all sorts of apparatus to fit the aperture and keep the patient dry, but they found that the Higginson's nozzle was more effectual than all perfect theoretical notions, and it took them some time to realize theoretically how such a simple contrivance was effectual.

The patient left the hospital on August 8, 1896. She came to show herself on March 17, 1897, with the apparatus in good working order, her skin quite dry and healthy, no urinary odor about her, and her linen clean and unstained. She can manage quite well, no urine escaping except a little sometimes at night when she is asleep. Her uterus is protruding, and they have recommended an advancement of the perineum to support it, but as far as the incontinence is concerned

the results have exceeded all their expectations. It supersedes completely the rectal reservoir idea, and does not come far short of affording all the advantages of the natural condition.

---

#### LIMITATION OF THE USE OF THE UTERINE SOUND.

H. DAUCHEZ (*La France Médicale*, No. 19, 1897) relates how, in an anomalous case of pregnancy, he fortunately refrained from the use of the uterine sound, although there were many signs and symptoms pointing to the presence of a myoma of the uterus. He thinks that the use of the sound should be reserved for those rare cases in which the gynecologist is able to convince himself *de visu* that the menstrual flow has occurred, or in which he is justified in believing his patient's statement that she has not run the chance of becoming pregnant. He quotes with approbation Gingeot's reflection that "the fear of the hystrometer is the beginning of wisdom."—*British Medical Journal*, July 3, 1897.

#### TUBERCULOUS ULCERATION OF CÆCUM GIVING RISE TO SYMPTOMS OF DISEASE OF THE APPENDIX.

HERBERT W. PAGE in *The Lancet* of July 3, 1897, places the following instructive case on record, for the simulation of the common symptoms of disease of the appendix was such as to leave little room for doubt as to the nature of the ailment for which the patient had sought relief, and for which operation was undertaken. Nevertheless, the appendix was free from disease, and tuberculous ulceration and narrowing of the cæcum were alone found after death to account for the symptoms. The case is therefore of further value in demonstrating that disease of the cæcum, and of the cæcum only, may cause symptoms likely to be attributed to the appendix, and that positive diagnosis may be in error. Happily, increase of experience is adverse to infallibility. In a recent paper in the *Clinical Journal*, entitled "A Demonstration on a Case of Appendicitis," Mr. Lockwood refers to a similar case which had been under his care, where he operated upon a youth who had had what every one considered to be two typical attacks of appendicitis. When the abdomen was opened it was found that he had acute tuberculous peritonitis, which was localized in the cæcum, in the vermiform appendix, the end of the

ileum, and the mesentery. Pain, which had been severe, was entirely relieved by the operation, but the patient ultimately died from acute general tuberculosis. The following is the author's own case:

A woman, aged thirty-six, admitted to the obstetric ward of St. Mary's Hospital on February 18, 1897, gave a history of having suffered from abdominal discomfort more or less for the past eighteen months. In May, 1896, she had an attack of pain in the right iliac fossa, accompanied with vomiting and constipation. Attacks of the same kind, two or three in number, but of less severity, followed at intervals, and in one which occurred shortly before her coming to the hospital a distinct lump had been felt in the iliac region. Uterine and ovarian disease had been excluded. The author was asked to see her, and under anesthetics was able to feel a small, hardish lump in the cæcal region. Local indications and history seeming thus to point to disease of the appendix, the patient was transferred to the author's care, with a view to operation as soon as the temperature became normal and quiescence should be established after her last attack. With careful dieting and rest in bed this was accomplished, and she became comparatively free from pain. The patient, although emaciated and pale, seemed to be in a favorable state for operation, but the author must acknowledge that he did not like the persistent hardness of the lump. There were scars on her neck from an old suppuration, but there was no present reason to suspect that she was the object of tuberculous disease.

The exploration was undertaken on March 30, the cæcum being exposed in the usual way and by the usual incision. It was at once obvious that no ordinary condition of things was present. Adhesions, old and firm, bound a tolerably hard lump the size of a hen's egg, which involved the cæcum, both to the abdominal wall and to the iliac fossa. The appendix was found and removed, but there was no trace of disease in it, and further exploration had to be abandoned by reason of the impossibility of separating the adhesions. Successful removal of the hard cæcal lump seemed to be out of the question; bleeding was therefore stayed and the wound was closed. The patient went on perfectly well for a few days, and then without apparent reason began to vomit. Local indications of wrong were markedly absent, but on the third day she suddenly collapsed and died in a few hours without attempt at

rally. Perforation was suspected, and the author deemed it useless to interfere.

The cæcum was much ulcerated and thickened by chronic inflammation, and at its juncture with the ascending colon was a stricture half an inch in length of almost cartilaginous hardness, and so tight as only to admit the passage of a small probe. Circumferential thickening and contraction accounted for this, and section showed that the induration passed into the surrounding areolar tissue after the manner of an infiltrating growth. On the cæcal side of the stricture there was extensive ulceration, and perforation had taken place at a point contiguous to it. No ulceration was found elsewhere. In front of the duodenum, in the position of one of the meso-colic glands, was a gland the size of a small flattened orange, which on section presented the aspect of caseous material, but was not soft. Another smaller gland lay close beside it. There was an old scar just below the apex of the right lung. Microscopical examination of the several diseased parts was made, and the appearance in the gland very strongly suggested tuberculous disease in the neighborhood. The bowel showed chronic inflammation, without sign of either sarcomatous or carcinomatous growth, and although not definitely tuberculous it was almost certainly of this nature. The stump of the appendix showed nothing more than some inflammatory thickening. Commenting on the notes Dr. Poynton remarks: "The case would appear to be one of chronic tuberculous ulceration of the colon and its junction with the cæcum, resulting in stricture, with secondary ulcers, which, from the slight amount of induration, were perhaps not tuberculous, but the result of the obstruction. The glands were affected in the same chronic way."

#### *TUBERCULOUS CYSTITIS.*

In treating this subject from an experience of 116 cases, Professor GUYON emphasizes first of all the immense importance of general therapeutics, which applies to all forms of cystitis. There is not the danger of irritating the bladder in tuberculous cystitis that there is in other forms, hence the diet should be abundant and extremely nourishing. Creosote ranks first in the medicines. He has also found cod-liver oil useful. Local treatment must be very cautiously applied as the bladder is exceedingly sensitive. It should be examined as little as possible and irrigation avoided. But the local treatment is

extremely important and should be commenced from the first, confining it to very weak solutions. He found boric acid, etc., injurious in any form, and restricts himself to sublimate and guaiacol. The sublimate is more effective; it is beneficial even in very weak solutions and in merely suspected cases. Four out of thirty-three patients treated with it were completely cured, five much improved, and eight moderately. He begins with a 1-to-5000 solution, raising this to 1-to-3000, and reducing the strength at the slightest evidence of irritation. It must always be borne in mind that the bladder cannot stand even the weakest solution in any form but gradual instillations: thirty to forty drops are enough; fifty the maximum. The general treatment should be continued months, even if all the symptoms have long ceased. The surgical treatment was high cystotomy in sixteen cases; one recovery, two improvements, seven deaths, and six negative results. Better results were attained with the perineal drainage. With this in seven operations five were very much improved, one died, and one was not affected. Nine women curetted *per urethram* were all very much benefited with one exception.—*Journal of the American Medical Association*, July 3, 1897.

#### MIDWIFERY AND DISEASES OF WOMEN.

H. LUDWIG, principal assistant in Chrobak's Clinic (*Wien. Klin. Woch.*, 1897, Nos. 11-12), records nine cases of rupture of the uterus. In the first the rupture occurred during the extraction of a decapitated breech; the head was subsequently removed by laparotomy. In the second the rupture was diagnosed before delivery, and Cæsarian section performed. In the third a rupture arose during version; the child was extracted, and the after-coming head perforated. The fourth was a case of craniotomy, which terminated the labor, after which the rupture was discovered. In the fifth, also, craniotomy was performed, the rupture not being diagnosed with certainty before birth. In the sixth there was again uncertainty; delivery was effected after decapitation. The last three were all diagnosed; they were delivered by craniotomy, perforation, and cutting through the cervical vertebræ respectively.

With regard to diagnosis, Ludwig insists on the valuelessness of individual symptoms such as collapse, bleeding, sudden and severe pain, recession of the formerly fixed presenting part, cessation of pains, etc. He has

found the best diagnostic signs to be: (1) in lateral rupture the interruption of the natural contour of the uterine quadrant, either a projection or a nodule being formed; (2) abnormal mobility of the uterus; and (3) emphysematous crackling at the seat of the rupture. If the head presents and can be pushed back, bimanual examination under deep narcosis should lead to a certain diagnosis.

With regard to treatment, delivery may be effected *per vias naturales*, or by laparotomy. The former is indicated when a large part of the child is already fixed in the pelvis, and also when the diagnosis of uterine rupture cannot be made with certainty before delivery. In cases in which the child remains in the uterus after the rupture, or has only partially passed into the abdominal cavity, delivery *per vaginam* is only to be preferred when it cannot be carried out without losing time or increasing or complicating the tear—for instance, in head presentations and the absence of contraction of the pelvis, also where rupture takes place during an operation. Laparotomy is indicated when the whole child has passed into the abdominal cavity, when the passages are not fully dilated, in contracted pelvis, in severe hemorrhages, and in injuries to the neighboring organs. In partial passages of the child into the abdomen, or with a living child still in the uterus, Cæsarian section is the correct procedure when natural delivery would take too long and be fraught with danger to the mother.

As regards treatment after delivery, of Ludwig's nine cases three came into the hospital and were operated on—two by supravaginal amputation and one by abdominal hysterectomy; all recovered. The remaining six were treated outside; five were operated on—four by supravaginal amputation, one by abdominal hysterectomy—of which one recovered and four died of sepsis. There was no death from hemorrhage except in the remaining case, which was not subjected to operative interference.—*British Medical Journal*, July 3, 1897.

#### TREATMENT OF VARICOSE ULCERS WITHOUT REPOSE IN BED.

With AUBOUIN's method the patient resumes his occupation without inconvenience or delay, and the dressings only need changing as the secretions find their way through the bandages. He first renders the limb aseptic and dusts the ulcer with iodoform, xeroform of aristol, or dermatol, smearing

the adjoining eczematous region with Lassar's paste (pulverized starch and white zinc oxide, each 20 grammes; vaselin, 40 grammes). After this Unna's glue paste, melted, is applied over the whole limb. (Formula: Water and glycerin, each 80 grammes; gelatin and zinc oxide, each 20 grammes). A starch tarlatan bandage is applied outside of this with moderate compression, and an outer bandage to prevent soiling, when the patient is dismissed to his usual occupation. The appearance of pus is the only indication for a change in dressings. They are easily removed after soaking in a warm foot-bath.—*Journal of the American Medical Association*, July 3, 1897.

#### THE PUBIC SYMPHYSIS IN PARTURITION.

EDWARD A. AYERS, in the *American Journal of Obstetrics* for July, 1897, after discussing this subject at length, gives the following directions:

Secure full dilatation of the cervix, if possible without risk to the child.

Have the urethra and bladder held to one side with a sound.

Make the initial incision a little above the subpubic arch and under the elevated clitoris.

Introduce the left index finger within the vagina, against the posterior groove or ridge of the joint, up to the top.

Pass a narrow tenotomy knife, with the point close to the joint, up to within a half-inch of the top, and under the overlying soft tissues.

Substitute a probe-pointed bistoury and meet the left index finger with the probe over the top of the joint, and work the blade through the joint downward until separation is felt by the posterior finger.

Have an assistant press the mouth of the wound and the tissues lying over the joint with a small piece of gauze.

Deliver with forceps, if possible, and refrain from suprapubic pressure, aiming to deliver the head through the cervix without drawing the latter down below the symphysis.

Hold the bladder well to one side while pressing the pubic bones together.

Pass a small strip of gauze into the prepubic wound, and another against the cervix, after irrigating, leaving both pieces exposed for easy removal, having refrained from stitching cervix or perineum.

Introduce a soft-rubber retention catheter into the bladder and leave it until sure the patient can voluntarily micturate.

Dress the vulva with gauze and strap the joint with adhesive strips.

Remove all the gauze in thirty-six hours and irrigate vulva and vagina twice a day, keeping the vulva carefully dressed between times.

#### ON EFFUSION INTO THE KNEE-JOINT.

DUER (*British Medical Journal*, July 3, 1897) gives the following simple manner of ascertaining the presence of a very small quantity of fluid in the knee-joint:

The knee-joint being slightly flexed, and laid on its outer side with the inner side in a good light, on making pressure with the hand above the patella the skin on the inner side of the patella will be seen to rise. In this way a small quantity of fluid which will not give a sense of fluctuation to the hands may be clearly demonstrated.

#### THE EXTIRPATION OF HIGH RECTAL CANCER.

HERBERT SNOW, in the *British Medical Journal* of July 3, 1897, details his method of procedure in high rectal cancer in the case given below:

H. B., aged fifty-seven, coachman, applied on May 5, 1896, with an advanced cancerous infiltration, apparently of four or five years' duration, high up the rectum. The forefinger could barely touch the border of a hard, woody mass, implicating the entire circumference of the gut; the growth was, however, very mobile. Cutting down on this in the usual way with gentle traction, the author made a small longitudinal incision through the diseased part, passed his left forefinger within the bowel, and was thus enabled to pull down the mass, dividing the healthy tissues above upon the finger-tip as a guide. Six inches was removed. The man made an uneventful recovery, and though troubled with fecal incontinence remains free from any trace of "recurrence"

If a malignant lesion high up the rectum be fixed, no operation will effect its extirpation; if movable, it will nearly always be found possible to radically excise it by the above plan without resort to the very severe measure which bears the name of Kraske.

Vulsellæ always tear through, whereas the finger thus used brings down the lesion without difficulty, while also controlling hemorrhage. There can be no more risk of sepsis than is involved in section of the bowel by any other mode.

*TREATMENT OF PENETRATING WOUNDS  
OF THE ABDOMEN.*

VULLIET (*Revue Médicale de la Suisse Romande*, July 27, 1897) has tabulated wounds of the belly treated by surgical intervention. These prove what has been abundantly shown before, that immediate operation is indicated when the viscera are probably wounded. The author in his endeavor to prove his case indulges in some ingenious statistical juggling which seems unnecessary and is certainly not convincing.

His *résumé* is as follows: Surgical intervention in case of penetrating gunshot wounds of the belly gives a gross mortality of 46.34 per cent. and what might be termed an expurgated mortality of 24.14 per cent.; abstention gives a mortality of 48.89 per cent. Penetrating wounds of the belly by cutting instruments treated by operation resulted in a mortality of 14.78 per cent., expurgated 10.09 per cent., whilst abstention resulted in a mortality of 37.04 per cent.

*SIX CASES OF LUPUS VULGARIS  
TREATED BY KOCH'S NEW  
TUBERCULIN.*

MORRIS and WHITFIELD (*British Medical Journal*, July 24, 1897) have published an elaborate paper detailing the history of six cases treated by Koch's new tuberculin. Koch's latest method of preparing his tuberculin is as follows:

Dry, virulent cultures are pulverized in an agate mortar. The powder is then diffused in distilled water and the fluid centrifugalized from the sediment, which is again dried and powdered and again centrifugalized, the process being repeated until no sediment forms. The fluid from the first centrifugalization he calls T.O., and it contains all the toxins of the old tuberculin. The other quantities of fluid derived from centrifugalization are similar in constitution, and he calls them T.R. It is this T.R., containing not the toxin but the components of the bacilli themselves, which is now in use.

Guinea-pigs were rendered immune by this fluid and then inoculated with virulent tubercle bacilli. They manifested no disturbance either locally or remotely. Guinea-pigs in which immunizing treatment was incomplete suffered from tuberculous glands near the site of injection, but no tuberculosis of internal organs. Those which were inoculated first and injected afterwards became tuberculous, but showed signs of healing as immu-

nity began to set in. In man lupus was much improved, and phthisis without great suppuration seemed to improve also.

Koch lays stress on the following points: Begin with a small dose ( $\frac{1}{100}$  milligramme). Raise the dose as rapidly as possible, taking care not to excite constitutional reaction. Never give a second dose until the temperature has fallen to the normal point or near it. Koch thinks immunity commences one or two weeks after the injection of the larger doses (0.5 to 1 milligramme).

Morris, summarizing the effects of the new tuberculin in the order in which these were observed, noted: (1) A diminution of the surrounding halo of redness in those cases in which this had been present to a marked degree before the commencement of the treatment; in cases in which there were simply yellowish-brown nodules in a white scar, the injections produced no visible effect at this stage. (2) The next change noticed was a slight depression in the center of the nodules, leading to wrinkling, and later to desquamation of the cuticle. Then there occurred (3) steady healing of all ulcerated surfaces; and (4) slow subsidence of the previously permanent edema of the lips, ears, etc. In two cases actual disappearance of the characteristic lupus nodules was observed—in one case on the upper lip, and in the other on the eyelid. In other cases there was distinct shrinking of nodules with diminution in the scaling of the surface. Another marked effect of the injections was the softening and flattening of preexisting scars. In no case has there been the slightest sign of progress in the disease since the treatment was begun. This fact is especially noteworthy in regard to one case, which had previously shown a very marked and ever-increasing tendency to recurrence and extension under so many forms of treatment.

As regards the immediate effect of the injections, there is at first little or no reaction, although in some cases a feeling of heaviness and drowsiness is complained of. When the larger doses are reached there is, as may be seen from the temperature charts, considerable febrile disturbance, sometimes with headache and pains in the limbs, and even some trouble in breathing, and a general feeling of depression with broken sleep. Locally the erythema is generally increased, and the whole affected area, including even old-standing cicatricial tissue, is swollen. In two cases, however, in which there were sound scars, probably from previous lupus, no re-

action was observed in the scar. The phenomena of reaction quickly disappeared, and then the patients without exception described themselves as feeling better than they did before. As showing how slight comparatively is the general reaction following the use of the new tuberculin, it may be pointed out that in two cases the patients were going about, and only came to the hospital from time to time to have the treatment applied. The authors, however, do not think that this course is advisable as a rule.

On the whole they find that the local effects of the new tuberculin in the cases of lupus vulgaris in which they have tried it have been uniformly good, in some cases distinctly brilliant. The constitutional disturbance has in no case been severe, and has always been of a very transitory character. As far as can be judged at present, the injections do no harm whatever.

#### *PURULENT OPHTHALMIA OF THE NEW-BORN.*

Of the many dangers threatening the newly-born infant, ophthalmia neonatorum is the most to be dreaded. It is stated that one-third of all the blind in Europe become so from this cause. Its early recognition and unremitting treatment are of the utmost importance. In every obstetric case the physician should gently separate the lids of the infant, to assure himself definitely of the presence or absence of any eye discharge. Infection from the maternal passages manifests itself almost invariably by discharge on the third day, both eyes being affected, as a rule. Discharges appearing at a later period usually arise from soiled hands, towels, sponges; and only one eye may be primarily attacked. This conjunctivitis is never due to strong light or cold, as is popularly supposed, but has a definite specific origin.

Following a discussion of the Medical Society of Breslau concerning Cr  d  's method of treating such cases with the aqueous solution of nitrate of silver (one grain to a drachm of distilled water), twelve thousand question blanks were sent out to physicians, with results that form an important contribution to the subject. These blanks were distributed throughout Germany, Austria, Switzerland, Belgium, and Holland. Reports were returned, giving statistics of eye diseases in 302,971 new-born infants. Of these, 1938 suffered from ophthalmia neonatorum. In Germany, sixty per cent. of eye diseases was

of this nature; in Austria, eighty per cent.; and in Switzerland, Belgium, and Holland together, ninety per cent. In all these cases the characteristic condition appeared within five days in seventy-six per cent. of the infants under observation. The discharge began after the fifth day in twenty-four per cent. In one-fourth of the entire number of cases, one eye was attacked primarily; in three-fourths, both eyes were affected simultaneously. Seventy-one per cent. were completely cured; nine per cent. discontinued treatment; twenty per cent., or one-fifth of the 1938 cases, retained permanent lesions of more or less severity.

This twenty per cent. with permanent ocular defects presented corneal scars, monocular or binocular; and one-half of these permanently damaged infants became totally blind. It was considered they were brought too late for cure—fifty per cent. of the blind babies were not seen until the ninth day of their disease, and twenty-five per cent. not until the fourteenth day.

Out of one hundred representative ophthalmologists consulted, seventy-nine were in favor of making Cr  d  's method obligatory in routine obstetric practise. It is not difficult, does no harm, and may avert dreadful catastrophe. The eyes are first carefully washed with tepid water, and the lids thoroughly cleansed by means of absorbent cotton. A few drops of the two-per-cent. solution of nitrate of silver are then instilled into each eye. Materials used to wipe away the discharge must be burnt or otherwise destroyed. Twice daily some simple ointment should be applied to the margin of the lids, to prevent them from sticking together. In severe forms, when there is much swelling and a thick discharge gushing from between the lids, the foregoing nitrate of silver solution may be used every six hours. When the inflammatory action subsides, Muskett recommends that weak solutions of alum, sulphate of zinc, and perchloride of mercury be substituted. The astringent lotion may consist of from four to ten grains of alum or from one to two grains of sulphate of zinc to the ounce of water. Either of these may be used with freedom and safety. The mercury solution gives excellent results—one-half grain of the perchloride to six ounces of distilled water. Cold-water compresses give great relief after active treatment.

Should ulceration of the cornea ensue, in spite of active and earnest measures, the eserine treatment introduced by De Wecker

may prevent perforation in even the worst cases. Four grains of eserine in one ounce of distilled water is the strength usually employed, though sometimes one grain to the ounce is better borne. A few drops are instilled into the eyes six times a day. This treatment is also of value in a form of corneal affection peculiar to infantile purulent ophthalmia, mentioned by Nettleship, in which the cornea becomes rapidly and almost entirely opaque. Whatever the degree of ulceration, marginal ulcers are not so serious as those centrally situated, and sight may be preserved. More than in any other disease, Dr. J. Lewis Smith urges the necessity of employing faithful and attentive nurses, who will carry out punctually the directions given. Two nurses are required, one for day and the other for night duty, since it is essential that the eye be frequently cleansed and the secretion washed away.—*Medical Record*, March 13, 1897.

**OPERATIVE TREATMENT OF CHRONIC  
INFLAMMATION OF THE MID-  
DLE EAR.**

MALHERBE (*Revue de Chirurgie*, June, 1897) having observed much improvement of hearing after free exposure and scraping of the mastoid antrum and auditory meatus in cases of chronic suppuration of the middle ear, has been led to apply a similar treatment with certain modifications to patients suffering from dry chronic otitis. Five cases are reported, in which the results of this treatment proved so satisfactory as to favor the assumption that exposure of the antrum and middle ear is indicated in cases of non-suppurative chronic otitis, which has not been relieved by other means. The main objects of the operation advocated by the author are free exposure of the mastoid antrum, which usually is contracted and surrounded by eburnated bone in cases where such treatment is indicated, and removal by gouge and mallet of the bone between this cavity and the middle ear. Any adhesions that may be found are carefully divided, so that the chain of ossicles may be set free. No attempt, it is stated, should be made to detach the base of the stapes from its normal connections. The following rules have been suggested to the author by the experience hitherto acquired of this treatment: Operative treatment, he holds, should not be attempted on patients of advanced age. In cases in which the operation is indicated it

should be performed early, before deafness has become pronounced, and subjective noises have increased to such a degree as to be almost intolerable. It would be useless to operate in cases in which there is no longer any cranial perception of sound. One ear only, and that in which the trouble is more severe, should be treated at the first operation. Experience has shown that an operation on one ear may be followed by an improvement on both sides.—*British Medical Journal*, July 24, 1897.

**OSTEOPLASTIC EXPOSURE OF THE ORBIT  
AS A MEANS OF FACILITATING RE-  
SECTION OF THE FIRST  
BRANCH OF THE  
TRIGEMINUS.**

CAHN (*Centralblatt für Chirurgie*, 1897) in a case of recurrence of orbital neuralgia removed the central stump of the already resected nerve by means of an osteoplastic resection performed through the orbit. The patient, fifty-two years old, suffered from right supraorbital neuralgia, for the relief of which the nerve was avulsed in the typical manner in 1893. The patient had relief for a year. Gradually pain returned and grew steadily worse. In 1897 the attacks of pain recurred every three to five minutes. In spite of morphine the patient could not sleep and was steadily losing strength. Pain recurred in the distribution of the supraorbital nerve, and tactile sense had returned. During the paroxysms of pain there was lachrymation. An incision was made along the right supraorbital ridge, but the nerve could not be found. From each extremity of this cut two vertical incisions were carried down to the bone; a skin, periosteum and bone lapping was chiseled loose and turned up. The remains of the spongiosa and the vitreous table of the frontal bone were removed, the dura mater was carefully lifted up, and the orbital wall of the cranial cavity was exposed. With a small chisel and cutting bone forceps the opening was enlarged. The frontal nerve with its clubbed, thickened end was found just below the periosteum; this was freed as far back as possible, and a little over an inch was torn over.

This was followed by iodoform tampon and reposition of the bone flap. There was no change in the patient's condition for two days. On the third day the pain gradually subsided, and on the sixth it was completely allayed. The wound was then closed by secondary suture and healed promptly.

The patient's general condition improved rapidly, and four months later he was completely well. There was no limitation of motion of the upper eyelid, nor were the motions of the eyeball interfered with in the least. On deep pressure into the orbit the opening could be felt in its upper wall.

This method is applicable not only to the extirpation of the first branch of the trigeminus, but also to the removal of foreign bodies which lie above or to the outer side of the eyeball.

---

**ARREST OF HEMORRHAGE IN HEMOPHILIA BY THE APPLICATION OF HEALTHY BLOOD.**

Dr. BIENWALD has employed this very original method in the case of a child aged two years, the subject of hemophilia. Having failed to arrest the hemorrhage from a small wound on the face by the application of perchloride of iron, he obtained some blood by aspiration from a healthy subject and deposited it on the wound. In a few minutes it coagulated, and the hemorrhage at once ceased. His explanation of the action of the remedy is that it supplies the ferment necessary for thrombosis in the small vessels. Whether this is correct or not it is impossible to say in the absence of definite knowledge of the pathology of hemophilia. As affording his explanation some support we may mention the success obtained by Dr. A. E. Wright in his experiments with a solution of fibrin ferment and chloride of calcium as a styptic. Dr. Bienwald's ingenious method certainly deserves a trial.—*The Lancet*, July 10, 1897.

---

**EXCISION OF THE RECTUM.**

PAUL (*The Lancet*, July 10, 1897) reports a second series of cases of excision of the rectum. A paper on the first series of fourteen cases was published in *The Lancet* of February 23, 1895. They were all malignant; thirteen were carcinoma and one was sarcoma. The present series is composed of two cases of syphilitic stricture, two of villous tumor, and ten of carcinoma.

In the first series of cases attention was called to one of squamous-celled epithelioma, which started in the mucous membrane of the bowel. In this series there is another. It occurred in a woman aged forty-seven years, and caused a tight stricture one and a half inches above the anus. It infiltrated the vagina, but evidently did not originate there,

as the vaginal mucous membrane was intact. Such abnormal forms of carcinoma probably grow in "rests" or in tracts of tissue such as give rise to rectal dermoids. Finally, in this connection, the evidence is again in favor of colloid being decidedly more malignant than cylindrical-celled carcinoma.

The methods of operation used may be arranged as follows: (1) Perineal incision, which suffices for the removal of about three inches of bowel—more in the female; (2) the same, combined with excision of the posterior wall of the vagina, which gives a great deal of room—the vagino-perineal operation; (3) posterior median proctotomy for the removal of small growths with subsequent suture; and (4) the sacral operation of Kraske. In none of these cases has the upper part of the rectum been removed by abdominal section.

Partial excision of the rectum through the perineum is a very successful operation. It is generally in these cases, in which the growth is small and situated near the anus, that we may hope for a long immunity. Growths higher up are longer in attracting the patient's attention, and the glands of the meso-rectum are often involved before they are recognized and sent for operation. If the patient is able to bear the complete operation it is always better to excise the entire circumference of the bowel in all cases in which the removal is too extensive to permit restoration of its caliber by suture. In those cases in which the writer has removed a growth from the posterior wall and left part of the anterior wall and anus, the discomfort from mucous discharge and prolapse has been considerable, and he has found it desirable to subsequently cut away all exposed mucous membrane. In fact, the subsequent discomfort from these slight operations has generally far exceeded that of the removal of six or seven inches of bowel.

The vagino-perineal operation is a good one, but it is of course essential to restore the vagina and perineum. The author once saw a patient upon whom this operation had been performed without restoration, and the result was deplorable, for the whole of the pelvic organs prolapsed from want of support. When the diseased parts have been excised the stump of the rectum is brought out at the posterior end of the wound, attached to a glass tube, the remains of the elastic wall of the vagina sutured in front, and deep silver sutures are passed between the two and a very long perineum procured. Generally the anatomical result is excellent.

The posterior median proctotomy for the removal of small growths with subsequent restoration of the bowel is perhaps the most interesting operation. A long backward incision is made, carried up over the sacrum if the tumor is in the middle third, and the bone is cut across and turned as a flap to the left side. The rectum is then opened in the middle line, and the disease examined with the finger. If it is a short stricture the entire circumference is excised; if an oval patch, then only the affected part. In either case restoration is best effected by sutures and not by Murphy's button. Having sewn up the wound made in the bowel for the removal of the growth the posterior lineal incision is closed, the sacral flap is restored, and the anus forcibly dilated to paralyze the sphincter. In some cases the result of this operation is nearly perfect.

The sacral operation of Kraske is, of course, the most serious. The incision is made as in the last case, the coccyx, or coccyx and lower part of the sacrum, being cut across and turned to the left. It is important to retain these bones, as when their support is lost the bowel may prolapse badly unless the special truss recommended in the previous paper is worn. Having exposed the bowel, if the growth is high up it may be cut across below, and the anus left intact; if not, dissect it entirely up from below. There is no value in the lower piece of bowel, only its removal makes a larger wound. Next, with constant use of compression forceps and aneurism needle below the knife or scissors, clear the bowel until the meso-rectum is cut away and the peritoneum freely opened; then draw down as much as is necessary to insert a glass tube above the growth, ligature it in, and cut off the latter. Enough bowel must be drawn down to allow the end to be brought out of the wound without tension. The sacral flap is then restored, the bowel connected to the skin with sutures, and the rest of the large wound in front packed with cyanide gauze.

The author states that he has tried by various ingenious methods to approximate the upper and lower ends after extensive removal, and is persuaded that any such attempt is bad practise when the excision exceeds two, or at most three, inches of bowel. The healing is longer and more dangerous, and the result little, if any, better. The use of a sacral flap in place of cutting away the bones is a distinct improvement. All the Kraske cases describe themselves as

having little or no loss of control over their bowels; in fact, they are more inclined to stricture than a patulous anus with prolapse.

The best result is obtained when a small growth or short segment has been removed and the parts have been satisfactorily united by sutures. The next best is after the complete removal of the lower end of the bowel, whether by the perineal, vagino-perineal, or sacral operations; it does not matter how much is removed, so that a clean end is brought out and the natural support of bones or perineum is made good. The worst anatomical results follow when a lot of exposed mucous membrane is left with a long slit-like anus, or when the support of the perineum or sacrum and coccyx is wanting.

Clinically there are many circumstances which influence the success of the operation, apart from the physical powers of the patient and the skill of the surgeon. The chief of these are: (1) Early recognition of the disease. This means that either it is low down or has rapidly formed a ring stricture. In the majority of cases the early symptoms are slight, and when the patient seeks advice the tumor is already large. (2) The nature of the growth. In innocent tumors the result should of course be cure, though in operating through the anus this does not appear to be the case with villous tumors. A villous tumor is generally a sufficiently serious affection to call for posterior median proctotomy. Of malignant tumors the usual cylindrical-celled carcinoma of the part offers the best prospect; squamous-celled epithelioma perhaps the next best; colloid and sarcoma the worst. (3) Involvement of glands. Wherever the writer finds malignant glands in the meso-rectum he always regards the case as certain to have a recurrence. Occasionally the glands may be recognized before operation, but usually they are concealed by the tumor. (4) Age. The younger the patient the less the chance of permanent cure. The rectum is the earliest of all sites for true carcinoma.

In regard to the survival of his cases after the operation, the author kept them under observation carefully. Of the first series of fourteen all were cases of malignant disease. One was certainly cured; several survived for from one to four years. Of the first fourteen cases of malignant disease, the last of which was operated on more than three years ago, two died from the operation; three are cured; one was under observation for ten years, and the other two for four years. One more he is almost certain is cured, although he has lost

sight of him after two years. The remaining eight averaged just two years of life after the operation, all of them dying from recurrence. In the author's judgment there are very few parts of the body where better results can be obtained when dealing with cancers of considerable dimensions.

In regard to the second series of fourteen cases, four are non-malignant; they are well and likely to remain so. Of the ten cancer cases two died from the operation, and two more have died since from recurrence—one at the end of twelve months and the other at the end of six months. This has been rather an unlucky series of cases, many of them having had enlarged glands in the meso-rectum at the time of the operation. He predicts that one only will prove a cure, a woman aged sixty-four years, who had a cylindrical-celled carcinoma  $2\frac{1}{2}$  by  $1\frac{1}{2}$  inches on the posterior wall of the rectum about two inches from the anus.

The mortality is exactly the same for both series—that is, fourteen per cent.

#### REMARKS ON CANCER OF THE UTERUS.

From observation of many cases, often seen too late for relief, and from the statistics of skillful operators, LANPHEAR (*International Journal of Surgery*, August, 1897) has reached the following conclusions as to the advice the attending physician should give his patients regarding operation:

As soon as a diagnosis of carcinoma of the cervix is made—provided the disease is unquestionably not too far advanced for any possible benefit at the time of first operation—radical operation is indicated.

Whenever there is a fungus growth upon the cervix (especially in a patient near the menopause) which persists in spite of treatment, even though there is no ulceration and but little tendency to spread. It is probably the papillary form of carcinoma cervicis; and there is always involvement of the mucous membrane of the body, so that high amputation will not cure.

When there are one or more nodules in the mucous membrane of the cervix, which soon ulcerate and destroy the mucosa. Such trouble is almost invariably the nodular variety of carcinoma of the cervix.

When there is an infiltrate in or beneath the cervical mucous membrane just within the os, which soon breaks down and destroys the cervix by erosion. It constitutes the variety known as cancer of the cervical mucous

membrane and may change when viewed through the speculum.

When there is evidence of the existence of cancer of the parenchyma of the uterus, even if the cervix seems to be perfectly normal. Such cases are not rare.

Whenever a glandular endometritis becomes inveterate, showing a tendency to degenerate into a typical malignant adenoma at the menopause; as indicated by (a) the appearance of irregular hemorrhages; (b) the presence of a serous, reddish, odorless discharge; and (c) paroxysmal pain.

In all cases where there is even a strong suspicion of malignant disease. In early operation lies safety.

Hysterectomy should not be performed under the following conditions:

Whenever the disease is so far advanced that the uterus is fixed in the pelvis.

Whenever it is certain there is extensive cancerous infiltrate in the broad ligament.

Whenever the cancer involves the bladder.

Implication of the posterior wall or even of the anterior part of the rectum is not necessarily a positive contraindication to operation.

When the "cancerous cachexia" has become pronounced.

When the patient is too weak from repeated, exhausting hemorrhages.

Whenever the diagnosis of sarcoma of the uterus is quite certain. Such cases always recur after removal and die quickly.

Palliative operation should be advised when there is marked sepsis; removal of the sloughing mass with the sharp curette and the subsequent use of douches of solution of permanganate of potash followed by insufflations of pyoktanin will greatly prolong life.

When there is excessive hemorrhage. In such cases curettage followed by cauterization and the after-treatment just mentioned will be of much benefit.

When pain is very severe. Even hysterectomy as a mere palliative measure is sometimes advisable, the pain being much less marked in recurring carcinoma in the pelvis.

#### THE RESTORATION OF MUSCULAR FUNCTION AFTER INJURY.

KNOTT in the *International Journal of Surgery* for August, 1897, publishes a paper with this title, in which he says probably the most common muscle injuries are wounds. We are concerned with only two varieties of

these—incised and lacerated wounds. The incised wounds of muscles are, as a rule, easily repaired, as there is little or no loss of tissue. The cut edges should be accurately adjusted with quilted catgut sutures, and the part immobilized for at least two weeks.

Lacerated wounds of muscles very frequently seriously threaten the future usefulness of the part. These wounds should be sterilized with unusual care, then cleared of all shreds of muscle tissue, and the severed edges trimmed so that they may be accurately sutured. If, after trimming the ragged edges, it is found that the destruction of muscle tissue has been too extensive to permit the approximation of the ends, the gap may be abridged with catgut sutures which will furnish a framework along which the connective tissue will more quickly and firmly close the gap than if no attempt at approximation is made. In a wound involving two or more muscles of a group, as those of the forearm or leg, care is necessary that the proper ends should be united. If only one end of a muscle so situated can be found, it may be sutured to an adjacent muscle having a similar function.

After repairing the injury to the muscles the underlying fascia should be carefully sutured to prevent hernia of the muscle, which may occur through a gap left in the fascia, and considerably impair the muscular strength. Should this occur it may be diagnosed by unusual prominence of the muscle at that point during contraction, and should be treated by freshening the edges of the rent in the aponeurosis, and neatly closing it with stitches.

Muscular contractions frequently follow improper attempts at repairing muscle injuries, or those injuries which result in the loss of considerable of the substance of the muscle, and may produce sufficient deformity or interfere so materially with muscular functions as to demand operative interference. This condition is best met by some of the various plastic operations upon the tendons.

Deposits of bone may occur in the muscle as the result of irritation produced by constant friction, or the presence of an excessive callus following fracture. Should this be very painful, or interfere with the muscular power, it should be removed.

The tendons are subject to much the same injuries as the muscle tissue proper, and if not properly treated muscular function and power may be seriously impaired.

In the process of repair of tendons the

new tissue generated is identical with that of the tendons themselves, and the rapidity with which this regeneration occurs depends upon the degree of approximation of the edges. When the severed edges are brought accurately together and retained with sutures firm tendinous union will occur.

Rupture of a tendon should always be treated by accurately suturing the divided ends with chromicized catgut, as owing to elasticity of the muscle the proximal end will be withdrawn some distance from the distal, and union will occur slowly and imperfectly, or not at all.

Several ingenious methods of suturing tendons have been devised, the object being to effect firm and perfect apposition of the ends. These methods are known as Le Fort's, Wolfier's, Esmarch's, Le Dentu's, and Trnka's, and are all quite similar.

The suture known as Le Fort's is at the same time the simplest and best of these, and is a method which the author claims he devised and used one year before Le Fort published his description of it. It is very easy of execution and is performed as follows:

Both ends of the divided tendon having been secured, a small needle armed with catgut is introduced about the middle of one side of the proximal end of the tendon, brought out in front, reintroduced, and brought out upon the opposite side. Then each end of the suture is introduced in the sides of the distal end of the tendon, brought out at the center, and firmly tied.

This suture retains the cut or torn surfaces in perfect apposition, allowing no gaping at the suture line, and may be very rapidly inserted.

Wounds of tendons are of frequent occurrence, and are often overlooked, the incision in the skin and fascia being closed, and no attempt made to repair the damage to the tendons. The tendons underlying any wound should be carefully examined before the wound is closed, and if severed should be united. If there has been no loss of tissue the two ends may be easily approximated and retained by the means described above, although it is frequently necessary to extend the incision to recover the proximal end, which owing to the contractility of the muscle is often withdrawn some distance from the wound. It may at times be secured and drawn down by introducing a narrow-bladed pair of forceps into the tendon sheath, seizing it and withdrawing them.

When so much of the tendon tissues has been destroyed as to prevent the direct approximation of the several ends, there are various ways and methods by which we will be able to restore the lost muscular power. If the ends of the tendon sheath can be brought into apposition, this should be done, as the tendon will regenerate along the path made for it. If the ends of the sheath cannot be united there are still several efficient methods by which we may remedy the defect. Several methods of lengthening tendons have been devised and practised, the best of which, for the condition under consideration, is Czerny's, which consists in splitting one of the pieces of tendon longitudinally nearly to the end, turning down the piece thus secured and suturing it to the other end. The tendon soon regains its original strength. Anderson's method of lengthening tendons is the best to employ where we desire to relieve a contracture of the muscle. A longitudinal incision is made in the center of the tendon of any desired length; then at either end of this incision an incision is made at right angles through the tendon, thus forming two flaps which may be adjusted to any desired length, and firmly sutured. If in a case of severed tendon with loss of tissue we cannot employ Czerny's method, we may connect the divided ends with strands of catgut, thus furnishing a framework for the regeneration of tendon tissues.

A good functional result may also be obtained by transplanting of a tendon, to take the place of the one destroyed. The material for the transplanting may be secured from the patient in some instances where the destruction of tissue has been very large; or if not, an animal tendon may be so utilized, and the usefulness of the part restored. In those cases where only one end of the tendon can be found its function may be restored by suturing it to a neighboring tendon, thus operating two members with one muscle, or combining the power of two muscles in one tendon. The best method to employ in this tendon anastomosis is that of Tillaux and Duplay, and is easily performed by splitting the intact tendon longitudinally, drawing the end of the divided tendon into this opening, and suturing fast. If the tendon has been completely destroyed in the case of the flexors and extensors of the hand or foot, the neighboring tendon with the same function may be split longitudinally in its center, one-half detached from its insertion, and sutured fast

at the point of insertion of the destroyed tendon, thus restoring the motion of the part.

We are often called upon to relieve the unsightly contractures or complete loss of function resulting from an old tendon injury improperly treated. In these cases the exposure of the two ends of the tendon is usually quite difficult, and can only be effected by patient dissection. When found they should be freshened and united by one of the methods described above.

In all operations upon the tendons the procedure should be rendered bloodless, as an unobstructed view is necessary for good work. The best suture for all cases is the continuous stitch, and the best material for the stitch is chromicized catgut.

After all cases of tendon suture the part must be immobilized for at least three weeks, that firm union may be established.

---

#### THE ULTIMATE RESULTS OF RADICAL CURE OF HERNIA.

TAILLENS (*Revue Médicale de la Suisse Romande*, July 20, 1897) holds that cure of hernia cannot be considered radical until a period of two years has elapsed since operation, and that even after three, four, or five years there may be recurrence. The cases recorded were those coming to the service of Professor Roux in the years 1890 to 1894 inclusive; in all 401 are noted. Of these only 324 could be followed.

In the statistics which are given all the cases have an operative age greater than two years. The operation in inguinal hernias consisted in freeing the sac a little beyond its neck, ligature, and excision. In 1893, in addition to this procedure the external ring was closed by suture, the needle taking in not only the external oblique and its fascia, but also some fibers of the internal oblique, leaving behind the cord only the transversalis fascia. Sutures were applied in a single layer. From about the middle of 1893 the operation of Bassini was practised, being modified only in that mattress sutures were used in place of the interrupted ones of the originator of the operation.

In crural hernias the sac was dissected and ligated. The external ring was then closed by several sutures, including all the soft parts down to the bone; that is, on one side the crural arch, on the other pectineal fascia and the periosteum.

Umbilical hernias when occurring in chil-

dren were closed by suture without resecting the sac. In the adult laparotomy was performed and regular suture in layers, the sac being first resected.

First, silk was employed, later catgut.

Suppuration occurred frequently, particularly in inguinal hernias.

Of 324 cases of radical cure, 270 were cured and 74 recurred, a percentage of 16.7; of 288 inguinal hernias, the percentage of recurrence was 16.7; of 22 crural hernias, 27.3 per cent.; of 14 umbilical hernias there were no recurrences.

As to the factors which influence recurrence, relaxed abdominal walls and weak muscles, direct course of a hernia through a large opening, thickenings of the cord, and advanced age of the patients, all exerted an unfavorable influence.

Bronchitis, bronchopneumonia and gastro-enteritis are complications which very seriously compromise the success of the operation, both in regard to ultimate cure and mortality.

There were 5.4 per cent. of recurrences in the children operated on under ten years of age; 5 per cent. of those operated on between ten and twenty years; 15 per cent. between twenty and thirty; 35 per cent. between thirty and forty; 31½ per cent. after 40 years.

Bassini's operation was less successful than that of simple suture, giving nearly thirty-six per cent. of recurrences as against a little over twelve per cent. by the last named procedure.

Of the 324 cases, 257 healed by first intention. The percentage of recurrences was 15.2 per cent. in those healing by first intention; 22.4 per cent. in suppurative cases. Suppuration was observed more frequently after Bassini's operation than that of simple suture. Of 288 cases of inguinal hernia operated on, there resulted in twelve instances atrophy of the testicle; in three hydrocele of the cord and testicle; in three varicocele. The atrophy was more frequent after Bassini's operation.

The author concludes with the statement that of the three varieties of abdominal hernia commonly encountered the umbilical is most readily cured. The crural is the one in which failure is most frequent. The likelihood of cure is proportionate to the youth of the patient. Suture of the columns of the external ring gives ultimate results much more favorable than Bassini's operation. Healing by first intention is more likely to result in cure than healing by granulation.

*A NOTE AS TO WHEN INCISION OF THE TYMPANIC MEMBRANE SHOULD BE PERFORMED IN ACUTE INFLAMMATION OF THE MIDDLE EAR.*

Sir WILLIAM DALBY discusses this important subject in the *British Medical Journal* of July 24, 1897. He calls attention to the fact that incision of the membrane when pus is believed to be within the tympanum has for many years been the established practise with surgeons. The real difficulty in these cases is to decide upon the precise period when the incision should be made. We are often unaided by any physical signs in the membrane, and in dealing with an infant we cannot elicit the physical signs within the tympanum as we can in the case of adults; neither can we get the additional help by interrogation as regards sensations which point to fluid within the cavity of the tympanum. When there is added to this difficulty the additional one of the smallness of the parts, the subject is not without its embarrassments. The physical appearances in the membrane are usually of no help in these cases, for they are often absent, and as frequently as not the most that can be seen to be abnormal are the appearances showing a closed Eustachian tube and perhaps some congestion of the vessels.

In the case of infants the constitutional symptoms and the demeanor of the little patient as indicating pain of an acute and agonizing character, or pain prolonged over many days, are the sole evidences within our hands. Taken alone the heightened temperature is an insufficient guide, for in all cases of pain in the ear in children depending on slight inflammation or even congestion of the tympanum, the temperature at once rises considerably.

In the large proportion of cases leeches and hot fomentations will cut short inflammations of the tympanic cavity, but it would be safe to adopt the rule that when they do not a vertical incision should be made in the posterior section of the membrane—a rule subject, of course, to the general aspect of the case.

The operation does no harm, although there may not be any pus to provide an exit for. The justification for the procedure is that there may be pus within the tympanum associated with an absence of physical signs of its presence in infants. In order to estimate properly the exceeding difficulty of offering the same kind of relief in cases of scarlet fever, measles, typhoid, etc., the char-

acter of the various courses which inflammation of the tympanum pursues must be studied closely.

In the infantile forms of this inflammation (not connected with the exanthemata) the process is often slow, subacute, the case dragging on day after day without the membrane giving way. When we consider cases of scarlet fever, measles, etc., we ought always, theoretically, to be able to prevent the ulcerative process by incising the membrane. Practically this is more frequently than not impossible, and for this reason: Perhaps in the evening the ear is not involved, and before morning breaks the inflammation has commenced, and the membranes, or one membrane, is perforated, so rapid is the process; or, again, in the desquamating stage the same rapid ulceration will take place. The damage will be done before the surgeon can be called in. In the case of adults whose tympanic cavities are inflamed, the whole subject is inordinately more simple and relief more feasible. It is easy enough to estimate the presence or absence of secretion within the tympanum, for the passing of air into the tympanic cavity gives the characteristic moist râle (through the otoscope) indicative of secretion. Also when the pressure of fluid has been brought to work changes in the aspect of the membrane, such as a discoloration in a circumscribed spot, or a generally sodden appearance, no further indication is required.

When this sodden appearance is present, and the knife cuts not crisply but as if passing through soaked blotting-paper, the opening thus made is frequently permanent, or at any rate remains for long periods; for the membrane has become so disorganized as to impair its tendency to repair.

#### OPERATIVE TREATMENT OF EXOPHTHALMIC GOITRE.

SCHULZ (*Berliner Klinik*, June, 1897) reports fourteen cases of Basedow's disease under the care of Kümmell, which were treated by partial removal of the enlarged thyroid body. In most of these cases the symptoms of this disease were very severe, and rendered life almost intolerable. Twelve of these patients, it is stated, were completely cured and enabled to resume their occupations. In the two remaining cases the operation was followed by much improvement, and there is every probability of the exophthalmus, the sole persisting symptom of the disease, dis-

appearing in a short time. There could be no doubt that each of these fourteen patients presented well marked and very decided symptoms of Basedow's disease. Frequent observation of the patients after operation during intervals varying in the different cases from two to seven years have convinced the author that objections to partial strumectomy on the ground of probable relapse do not hold good. In one case only was there observed any renewed enlargement of the thyroid. In all the others the remaining portion of the gland showed a tendency to shrink rather than to increase in size.—*British Medical Journal*, July 24, 1897.

#### A CASE OF DRY GANGRENE OF BOTH LOWER EXTREMITIES COMPLICATING ORDINARY SCARLET FEVER; DOUBLE AMPUTATION; RECOVERY.

LITTLEWOOD (*The Lancet*, July 10, 1897) reports an interesting case of gangrene occurring in a boy aged four years, who was admitted to the Leeds City Hospital on September 14, 1896, suffering from scarlet fever. On admission the child presented the ordinary symptoms. On the ninth day numerous small discolorations were noticed extending over both lower limbs from the toes to within two or three inches of the knees anteriorly and posteriorly. The scarlet-fever process followed a favorable course, except that day by day the discoloration of the limbs became more marked, though continuing patchy, lividity being most intense at the toes and feet, and becoming less so from below upward. On the twelfth day the limbs retained a considerable degree of warmth, probably somewhat exaggerated by the more or less continuous application of artificial heat, but in neither limb could pulsation in the femoral arteries be distinctly felt. Pain now appeared, apparently of an intermittent character, and the discoloration had spread to some four inches above the knees anteriorly and to slightly above the center of the popliteal space posteriorly, the distribution being almost exactly similar in both limbs. During the next five days the temperature subsided to the normal. Five days later an oblique line of demarcation had formed, roughly extending in both limbs to three inches above the knees in front and to the center of the popliteal spaces behind. At this time cardiac dilatation was noted, together with a suspicion of roughness of the first sound at the

apex. Amputation was accordingly advised and carried out by a modified circular operation. All the available healthy skin above the gangrenous part was retained, an incision being carried upwards on the outer side for some four inches. The femur was divided at about the junction of the middle and upper thirds. The blood was very thin, coagulating slowly and imperfectly. The femoral artery was patent. Silkworm-gut was used for stitches, and the dressings were cyanide gauze and iodoform. Recovery followed this operation, and a week after amputation through the left thigh was performed, with like anesthetic precautions and incisions. The patient bore this operation much better than the first. The wounds were similarly drained and stitched, and they also healed by first intention. After the second operation the patient made rapid progress and was allowed to be wheeled about in the ward on November 3. When seen later at his home the stumps were found to be well padded. He had free power of flexing, extending, abducting, and adducting the stumps and would shortly be able to wear artificial limbs.

#### RESECTION OF THE LIVER.

AUVRAY recommends applying to the liver around the portion to be removed a series of interlocked ligatures of thick silk. To apply the ligatures he makes use of a blunt pedicle needle with a long curve to it. Each individual ligature, after being crossed with its fellow to the right and left, is slowly and steadily tied with such firmness that the liver parenchyma is cut, but the vessels are retained undivided in the loop. When the whole series of ligatures are tied the vessels are to be severed by the knife or scissors. It is of importance while transfixing the liver to use little force, and when any slight obstacle to the passage of the instrument is encountered, to manipulate the needle from side to side, and so gently guide it past the obstruction. Such obstructions are usually large vessels, and any force used might cause them to be perforated. The points of transfixion ought to be about one centimeter apart. In his experiments Auvray has never met with any difficulty, and has never found that the wound in the liver bled in the slightest degree, either primarily or secondarily.

Auvray's experiments were made on living dogs and on recent human cadavers. Seven dogs were operated upon. Of these two died

from chloroform as the operation was being finished. The rest recovered rapidly and were killed for examination at periods of from two to thirty-one days after the operation. In all the cases which survived the anesthetization adhesions were found between the wound in the liver and neighboring organs. These adhesions were formed rapidly, since in a dog sacrificed forty-eight hours after the operation they existed between the omentum and the anterior surface of the stomach. The wounds in the liver healed rapidly. In an animal which was sacrificed after thirty-one days the portion of liver removed had been regenerated, thus confirming anew the observations of Ponfick and others.

Experiments made on recent human cadavers were equally satisfactory. After the ligatures were applied and the portion of liver supposed to be the seat of tumor was removed, injection of the liver with colored fluid did not show any leak in the wound. To test the firmness and safety of the ligatures traction was made upon them, with the result that the vessels were partially pulled out from the parenchyma behind the ligatures, but these latter did not slip.

Auvray suggests that it might be well in excising portions of the liver to make the wound wedge-shaped so that, hemostasis having been obtained by ligatures, the wound might be made less extensive by means of sutures passed from side to side.—*Annals of Surgery*, August, 1897.

#### COLOPEXY FOR THE RELIEF OF PROLAPSE OF THE RECTUM.

BRYANT (*Annals of Surgery*, August, 1897) thus operated in a case of inveterate prolapse of the rectum, which had not been materially benefited by the formation of an artificial anus.

An incision three inches in length, parallel with Poupart's ligament, was made down to and through the peritoneum. The peritoneum was separated from the superimposed tissues at either side for an inch at least, but farther above than below. The gut was pulled upward firmly, causing the prolapse to disappear entirely; and while the gut was thus held, effort was made to draw down any relaxed tissue of the rectum that might be within reach. The mucous membrane only was relaxed, but not to a sufficient degree to permit its appearance at the anal opening. During firm traction upward on

the gut the peritoneal flaps of the wound were joined to it by quilting and continuous sewing with silk, the stitches including the muscular coat of the intestine. Six silk sutures were then carried through the borders of the abdominal wound, and so as to include the muscular coat of the gut, behind the longitudinal band. The longitudinal band was then drawn forward into the wound almost to the external limit, and the sutures tied firmly, thus causing the border of the wound to grasp firmly the entire band and some portion of the intestinal wall. The wound healed promptly without untoward manifestation. The patient was kept in bed for three weeks, since which he has been allowed entire freedom of action in all respects. No protrusion has been seen after defecation or with the severest strain since the operation.

As a result of the operation the patient was apparently cured, but later developed a hernia at the seat of incision. Bryant has collected twenty-nine cases of this operation with seven recurrences. There were no deaths. He offers the following conclusions for consideration:

That the results in the experience of others with colopexy, and the present outcome of this case, bespeak a continued effort in this direction, with a well founded belief in the attainment of beneficent results in proper cases.

That the brief duration of many of the cases at the time of report and the varying methods of fixation of the bowel to the abdominal wall bespeak further experience in these matters before positive conclusions are expressed.

That fixation of the bowel by sewing it to the deep tissues of the abdominal wall at a point independent of, yet conveniently near to, the incision offers a satisfactory method of anterior fixation.

#### TENOPLASTIC SURGERY.

BRADFORD (*Annals of Surgery*, August, 1897) by the above title implies not only suture of traumatically divided tendons, but the securing of the distal cut end of the tendon of a paralyzed muscle to the proximal end of the tendon from a strong one. This form of transplantation was suggested first by Nicoladoni in a case of infantile palsy of the ordinary type. It is necessary not only to correct the deformity but to restore the balance of the muscles to prevent a recur-

rence of the deformity—for instance, transplantation of the peroneus longus into the tendo Achillis, into the tibialis posticus, and into the anticus; the union of the tibialis anticus with the extensor proprius pollicis; shortening of the extensor tendons of the toes; shortening of the tendo Achillis; lengthening of the tendo Achillis; and insertion of the sartorius muscles into the rectus femoris tendon. When the tibial group of muscles is weakened the tendon of the peroneus longus may be transplanted; the sheath of this tendon is opened slightly above the level of the malleolus, the tendon pulled out and cut across, and at least two inches of its proximal end freed. This end is passed beneath the tendo Achillis and secured by suture to the distal end of the divided posterior tibial tendon. The method of suturing the tendon is of importance, since the tendinous structures may be supposed not to unite as readily as other tissues, as their vascularity is less and the strain to which they are subjected is great.

Following the operation supports should be used which will constrict as little as possible. The foot or limb should be placed in such a position as to relieve the muscles and tendons operated upon from any strain. Besides the ordinary aseptic dressings, the limb should be covered with sterilized sheet wadding, and the foot and limb held in plaster-of-Paris bandage. It should remain in this until union is expected. The immediate result is always successful so far as recovery from the operation is concerned. Where ordinary judgment is used, and healthy tendons are sewn to paralyzed ones in a proper manner, there is always a recovery of motion in the paralyzed tendons attached to an active muscle as soon as the wound is healed. This recovery may be regarded as permanent. The actual benefit should depend on the strength of the muscle utilized as well as the part operated on.

The author announces that he and his colleagues have performed transplantation in twenty-seven cases of infantile paralysis, chiefly those requiring transplantation of peritoneal tendons. In two cases little benefit followed; in the remainder there was a gain of the hitherto restricted motion, this gain being increased under use.

Tenotomy and myotenotomy with resulting tendon lengthening have been performed in nineteen cases of spastic paraplegia and hemiplegia with, in most instances, satisfactory results.

*A SIMPLE PROCEDURE 'BY WHICH AN EASILY MANAGEABLE ARTIFICIAL ANUS CAN BE MADE AFTER COLOTOMY.*

BEYER (*Prag. Med. Woch.*, No. 8, 1897) so plans his incision through the belly walls that the cut through the peritoneum lies parallel to the skin incision but one and a half inches upward and inward from it; thus the opening is oblique. The sigmoid flexure is drawn out and secured to the parietal peritoneum, then to the borders of the abdominal muscles, after which the greater portion of the skin wound is closed. The remaining portion of the gut is then drawn forward, opened, cleansed, and secured to the skin edges.

THE POCKET THERAPIST. A Concise Manual of Modern Treatment, for Students and Junior Practitioners. By Thomas Stretch Dowse, M.D.  
Bristol, England: John Wright & Co., 1897.

The author states that he has put forth this manual with the belief that it may be useful to the student and young practitioner in the exercise of his calling. His suggestions as to the treatment of disease are, he states, based on experience. He has referred only to remedies which he has found useful, and left unnoticed those which he has found useless. The book is arranged in alphabetical form, so that the diagnosis having once been made the practitioner by using this book as he would a dictionary is enabled at once to select appropriate treatment. Thus, if the physician is consulted by a person suffering from baldness, by turning to this word, which is done in an instant, since the book is small, he discovers that washing with borax and water night and morning, followed by a lotion containing jaborandi, cologne, oil of almond, oil of rosemary, and some other ingredients, is the appropriate treatment. Appendicitis is relieved by hot fomentations and small doses of extract of opium and absolute rest, purgatives being avoided. Proctitis is treated by injections of opium followed by lumps of ice in the rectum and injections of lead and opium. Keloid calls for hypodermic injections of thiosinamine.

On glancing through the book, the reader is impressed with the large number of drugs mentioned, some of them strange to American ears; thus branelcane, vibrona and sanmetto are commended. We believe the author would have done better to have limited the work strictly to the line of therapeu-

tics and to have given the results of his own experience. In even the small space of this handbook there are many quotations from others in regard to remedies, the curative effects of which have been quite disproven.

ATLAS AND ESSENTIALS OF BACTERIOLOGY. By Prof. K. B. Lehmann and Dr. Rudolf Neumann. Illustrated.

New York: William Wood & Co., 1897.

The greater part of this handbook is made up of some sixty-three plates printed in different colors, most of them containing several figures illustrating the growth and microscopical appearance of the various pathogenic bacteria. The descriptive matter for each plate is printed on the page facing it. This portion of the work is followed by 130 pages of text devoted to the morphology of bacteria, their clinical composition, vital conditions, formation and germination of spores; the effects of bacteria, especially in regard to their employment for diagnostic purposes; the chemical action of bacteria metabolism; the pathogenic effects of bacteria; and an appendix, including microscopical examination, the most important solutions for making preparations, the preparation of stained specimens, section preparations, culture of bacteria.

It is evident that this book is likely to be extremely useful, especially to those practitioners of medicine who have received such elementary instruction in bacteriology as is now a part of the curriculum of every school.

Lehmann and Neumann are both so well known in the scientific world that their names are sufficient guarantee as to the fidelity of the illustrations. They have been more than usually successful in clearly presenting the essentials of the subject in brief space.

THE AMERICAN ACADEMY OF RAILWAY SURGEONS. Report of the Third Annual Meeting, held at Chicago, September 23, 24, and 25, 1896. Edited by R. Harvey Reed, M.D.

Chicago: American Medical Association Press, 1897.

This work, a copy of the proceedings of the third annual meeting of the American Academy of Railway Surgeons, contains some important original papers and the discussions which they called forth. Among the communications of special interest are: First Aid in Railway Emergencies, by James E. Pilcher; Medical and Surgical Expert Testimony, by John E. Owens; Medico-Legal Aspect of Floating Kidney, by R. Harvey Reed; Delirium of Shock, by R. Sayre Harnden; Burns and Scalds, by C. K. Cole; Perforating Wounds of the Eyeball, by D. C. Bryant; Penetrating

**Wounds of the Eye: Their Diagnosis, Prognosis and Treatment, with Especial Reference to Railway Employees,** by Archibald G. Thomson. Dr. R. Harvey Reed is to be especially commended for his admirable editorial work in the compilation of this useful volume.

**TUBERCULOSIS OF THE GENITO-URINARY ORGANS, MALE AND FEMALE.** By N. Senn, M.D., Ph.D. Illustrated.

Philadelphia: W. B. Saunders, 1897.

As in all of Senn's work, this book shows wide clinical experience and extensive knowledge of the literature of the subject. The first part of his work is devoted to Tuberculosis of the Male Genital Organs. Some interesting cases are quoted, but the teaching is not different from that laid down in the ordinary text-book.

In recent cases of tuberculous epididymitis parenchymatous injections of iodoform and glycerin emulsion or of chloride of zinc should be used. If this treatment does not prove satisfactory after a fair trial, castration should be performed before the disease extends to additional organs; in limited abscess formation the use of a sharp spoon and an iodoform gauze tampon may prove efficient, but if the disease resists these measures castration is strongly indicated. If the disease is bilateral, palliative treatment should take the place of radical operation in the majority of cases. Castration is absolutely contraindicated when the tubercular affection of the testicle is complicated by tuberculosis of any important internal organ. Simultaneous tuberculosis of the prostate and the seminal vesicles does not necessarily contraindicate castration.

In the treatment of tuberculosis of the female organs of generation, minute attention is paid to improving the general health. Guaiacol and creosote are especially commended, the former drug appearing to render harmless the toxins of the bacilli; it is given in doses of five drops in milk three times a day. Locally the abscesses are tapped under antiseptic precautions, and washed out with a five-per-cent. boracic acid solution; after this two to four drachms of a ten-per-cent. iodoform-glycerin emulsion should be injected. Theseappings should be repeated every week or two. Tubercular ulcers of the vulva and the vaginal portion of the cervix uteri should be curetted and thoroughly rubbed with iodoform. Tuberculosis of the vulva, vagina, uterus, and Fallopian tubes and ovaries is taken up in turn.

Finally, infection of the bladder and kidneys is considered. A detailed and very clear description of the operative technique required by nephrectomy closes this work.

No doubt the name of the author will assure this book a cordial reception on the part of the profession; even were it written by one quite unknown in surgical literature its great value would be immediately recognized.

**A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS.** In Photo-lithochromes from Models in the Museum of the Saint Louis Hospital, Paris. With Explanatory Woodcuts and Text. By Ernest Besnier, A. Fournier, Tenneson, Hallopeau, Du Castel, Henri Feulard, and L. Jacquet. Edited and annotated by J. J. Pringle, M.B., F.R.C.P. Part X.

Philadelphia: W. B. Saunders, 1897.

This number contains photo-lithochromes of Polymorphous Syphilides, with Predominance of Lichenoid and Miliary Forms; Paget's Disease; Trophic Ulcers of the Hand and Forearm; Syphilitic Chancre of the Face; Syphilitic Chancre of the Breast (Common Form); Syphilitic Chancre of the Breast (Ulcerative Form). Of these plates those representing miliary syphilis and extragenital chancres are unusually fine.

If the remaining parts of this admirable work are as perfectly executed as those which have already been issued, this Atlas will be the most serviceable and reliable one which the practitioner of medicine can procure.

### LONDON LETTER.

BY RAYMOND CRAWFORD, M.A. OXON., M.D., M.R.C.P. LOND.

Of matters medical in the current month there is but little to chronicle. London is deserted by its medical men, many of whom have made their way over sea to Montreal. Hospitals are dismantled, libraries closed, and the medical societies are enjoying a prolonged rest from their labors. The medical journals have caught the spirit of the season, and supply no more solid pabulum than the time-honored grievances of the profession against the world in general, along with the internecine struggles of the medical brotherhood. Prominent spaces are devoted to presentations of silver-headed canes to medical men by the grateful members of ambulance classes, and other matters of medico-social or medico-ethical interest. Among the latter

we note constant allusions to the existing state of depletion of the Army Medical Service. The medical profession thrives on martyrdom, and we hesitate to lighten the burden of its voluntary cross. In medical circles some sort of boycott of the Army Medical Service has been established just at a time when the struggle for a livelihood is keenest among the younger members of the profession. We submit that such an attitude is extremely ill-advised. The grievance is that medical men are not accepted on terms of equality by their brother officers. The fact is substantially true, but we must look behind the fact. Have we given the best of our material to the services? We think not. It is notorious that a medical man of education and social refinement meets a warm welcome among his brother officers, and we should hesitate to coerce their friendship to those of a less delicate social fiber. On the other hand there is no disposing of the undisguised and supercilious disregard with which certain department chiefs have sought to degrade the medical service in the eyes of the army and of the public. It would seem that as usual the fault and its remedy lie betwixt and between, and the more readily we set ourselves to mend our own shortcomings, the more easily shall we coerce the recognition of the War Office. But without any attempt to apportion duly the blame, we do not hesitate to protest against the introduction of the policy of settlement by strike into the medical profession. The commercial aspect of our calling is necessarily always near the surface, and it is ill to multiply its trade associations.

It is a matter of general regret that the leader of the House of Commons has been driven into sacrificing the London University Commission Bill. The question must now stand over for settlement to another year, and London must remain the only great city of the world without a university worthy the name. Seeing that some general broad line of settlement had been arrived at, it was hoped that a bill in which the interests of so many and important educational bodies were bound up might have successfully encountered the inevitable obstacles of individual opposition. It is true that the settlement, though not actively obnoxious to any one, was equally devoid of any special attractiveness for any one; but where so many opposing interests have to be satisfied it is clear that the latter condition can be more easily attained than the former. We gather, too, that

the bill has been withdrawn not with a view to amendment or alteration, but because it was necessary to sacrifice some innocent to the exigencies of the parliamentary timetable. The supreme body in the new university would be the Senate of fifty-six members, of whom about one-fifth would definitely represent medical interests. Students are divided into two classes—internal and external. Internal students are those who have matriculated at the university, and who are pursuing a course of study approved by the university in a school of the university, or under recognized teachers of the university. The interests of internal students are to be guarded by an Academic Council of twenty, who shall act as an advisory body to the Senate, while those of external students are to be entrusted to a Council for External Students consisting of twenty-eight members. Thus absolute control is vested in the Senate, acting under the guidance of two large sub-committees of its own members.

In the King's College Hospital reports, which have just been issued, Mr. Burghard has an instructive paper on the Treatment of Hydroceles in Children. He puts no faith in the methods of treatment by the application of evaporating lotions, or in puncture of the hydrocele by the triangular needle, so as to let out the fluid from the tunica vaginalis into the tissue of the dartos from which it is absorbed. The method he has adopted, and with marked success, is the injection of pure carbolic acid into the tunica vaginalis; this procedure is a modification of the method introduced by Dr. Levis, of Philadelphia, in 1881. The technique of the injection is as follows: An ordinary hypodermic syringe is filled with liquefied carbolic acid, made by liquefying the ordinary crystals of the acid by means of heat, and adding five per cent. of glycerin in order to prevent the carbolic acid crystallizing either in the syringe or in the needle as it is being injected. The hypodermic needle, duly sterilized, is then introduced into the tunica vaginalis through the skin, and the contents of the hydrocele drawn off. The needle should be rather larger than that usually employed for hypodermic injections. When the fluid has escaped the syringe is fitted to the needle, and a quantity of carbolic acid varying from five to eight minims, according to the size of the hydrocele and the age of the patient, is injected into the sac. It is important that during the injection the point of the needle should not be allowed to escape

from the tunica vaginalis, or the acid will find its way into the surrounding tissue and may be absorbed, or even lead to local sloughing. After the acid has been injected the needle is removed, and the walls of the tunica vaginalis are gently rubbed together so as to bring the acid into contact with every portion of the wall. The operation is very much less painful than when tincture of iodine is used, and after the preliminary puncture the child will often not cry at all. No dressing need be applied. After a few hours a more or less solid swelling replaces the hydrocele, and with it there may be some redness of the skin, but the constitutional disturbance is trifling. This swelling usually begins to subside about the third or fourth day, and disappears about the seventh or the tenth day; a swelling of longer persistence usually indicates a recurrence of the hydrocele. In none of the cases thus treated was there any symptom of carbolic poisoning, nor any tendency to sloughing of the scrotum. This is rather remarkable, seeing that children are very susceptible to absorption of the drug when used in watery solutions, even by the unbroken skin. On the other hand, the pure liquefied acid may be applied to extensive areas without inducing any toxic symptoms. Before adopting this treatment, and especially if the hydrocele seems to be secondary to some affection of the testis or to an inflammatory condition of the scrotum, it is always well to see whether the hydrocele may be cured by treating its cause.

Mr. George Cheatle records some good results in the treatment of gonorrhea by a novel but simple method. He eschews all medicines and injections. The penis is well washed twice a day in a 1-in-60 solution of carbolic acid, and kept wrapped in cyanide gauze, wrung out of the same solution. The discharge is thus received into an antiseptic dressing so that it does not inoculate other mucous surfaces, and does not become secondarily infected with ordinary pyogenic micro-organisms. The penis and its dressings are inserted into a carbolized mackintosh bag attached to the suspender with which the testicles are supported even in the absence of any epididymitis. The patient is strictly instructed to soak his hands in the carbolic solution before touching his dressings for any purpose whatever. With cases so treated from the first the disease usually runs its complete course in fourteen days; in cases of longer standing the ultimate results are just as good, but require a longer appli-

cation, while gleet in addition generally requires local treatment with the aid of the urethroscope. Mr. Cheatle claims for this method that it minimizes the septic complications, such as abscesses in the groin, and otherwise favorably determines the course of the disease.

Mr. Watson Cheyne records an interesting case of simultaneous wiring of both patellæ for fracture. The fracture of the right patella was transverse, and due, as is usual, to the sudden contraction of the quadriceps muscle snapping it across the condyles of the femur; there was a similar transverse fracture of the left patella, similarly produced, and in addition a vertical fracture due to direct contact with the ground. Three days after the accident both patellæ were wired in the usual manner, the upper and lower fragments on the right side being united by a single thick wire; on the left the two halves of the lower fragment were first bound together transversely, and then wires were passed from each half to the upper fragment, so that in all four wires were used. The wounds were stitched up without any drainage, and no splint was used as the patient was encouraged to move his leg freely in bed after the operation. He was discharged from the hospital after four weeks able to walk quite well, and a month subsequently was able to walk or run as usual; in fact the knees were as perfect as before the operation. The wires could still be felt under the skin, but had given rise to no trouble whatever.

On the treatment of flatfoot Mr. Carlars speaks as one having authority. Every one must have been impressed with the futility of the methods commonly in use to meet the requirements of the severer cases. True, there are not a few cases in which the yielding of the arch is but part and parcel of a condition of general enfeeblement, and such may be relieved by measures directed to the improvement of the general health. Other cases require nothing further than a simple mechanical support of rubber, cork, or spring metal. But there remains a variety of cases which can only be relieved by active operative interference. Mr. Carlars has discarded such measures as pegging the astragalo-scapoid joint, or removal of a wedge-shaped portion of bone from the neck of the astragalus, for a method suggested by Willett, of St. Bartholomew's Hospital, from which he has had excellent results in several cases. He describes his procedure as follows: The patient is anesthetized and the

foot is grasped from the inner side in such a way that the two thumbs rest on the inner aspect of the head of the astragalus, while the rest of the hands pass respectively over the anterior and posterior segments of the foot. The part is then forcibly wrenched into a position of extreme adduction around the head of the astragalus, which is fixed by the two thumbs as a pivot. In this way the anterior segment of the foot is deflected from the direction it has acquired by drawing the scaphoid, as it were, over the head of the astragalus. The foot is then fixed in its new position by a wrapping of plaster of Paris for several weeks, and at the end of this period the patient can usually walk about freely. Mr. Carlers maintains that the pain which subjects of flatfoot often complain of on the inner aspect of the arch is due to tenosynovitis of the tibialis posticus tendon. This is sometimes evidenced by the presence of a diffuse tender swelling along the course of the tendon, in which fluctuation may be detected above and below the annular ligament. For this condition he recommends either rest and blistering or the more radical treatment of laying open the sheath, washing it out and draining, and if desired, in connection with the wrenching process.

At the end of last month the Royal College of Physicians made a notable contribution to the Jubilee celebrations by the admission of the Prince of Wales to an Honorary Fellowship of the college. The ceremony was performed at Marlborough House, and not as usual within the walls of the college. After the ceremony of admission by Sir Samuel Wilkes, as President, the Prince was presented with a diploma on vellum, illuminated with the college arms, and wrapped in a case of red morocco. An additional and more useful presentation was that of a gold-headed cane, of the pattern formerly carried by every physician of learning and position, with a vinaigrette in the head to ward off the perils of infection. The text of the diploma is couched in language which while failing to carry our thoughts reflexly back to the glories of Augustan Latin literature, at any rate suggests an easy transition from the existing diversity of tongues to a universal language, and is as follows:

*Sciatis omnes nos:* Samuelem Wilks, Baronetum, Medicinæ Doctorem et Præsidentem Collegii Regalis Medicorum Londinensis, una cum consensu Sociorum ejusdem Collegii, auctoritate nobis a Domine Rege et Parlamento concessa, in Societatem nostras, honoris causa, cooptasse virum illustrissimum Albertum Edwardum, Walliæ Principem, Corombiæ Ducem, Nobilis-

simi Ordinis Periscelidis Equidem. In cujus rei fidem et testimonium Sigillum nostrum commune præsentibus apponi fecimus. Datum Londini in Collegio nostro die vicesimo nono mensis Julii, annoque Domini millesimo octingentesimo nonagesimo septimo.

### PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

Most American physicians who have visited Paris have not failed to pay a visit to the Clinic of Dr. Luys, at the Charité Hospital. This clinic, which was frequented not only by medical students and physicians but also by many persons not belonging to the medical world, including reporters, was the scene of some of the most curious phenomena of hypnotism, to which Dr. Luys had especially devoted himself. A favorite exhibition was the effect produced by solutions of drugs in bottles brought into the neighborhood of patients in the hypnotic condition. As the patients shown by Dr. Luys were more or less the same, and by constant repetition had become educated in the various manifestations which were expected of them, it was natural that accusations of imposture should be made. It may be said, however, that all who were acquainted with Dr. Luys considered him to be perfectly honest in his opinions, and at the worst mislead by too great a belief in the honesty of his patients.

Dr. Luys, who retired not long ago from the post of hospital physician, but who still occupied himself with practise, died suddenly during the holidays, while at a watering-place.

In 1888 and 1889 Dr. Luys published two works on his favorite subject—"Emotions chez les Hypnotiques" and "Leçons Cliniques sur les Principaux Phénomènes de l'Hypnotisme."

It is well known that one of the most difficult conditions to treat is that of chronic constipation. The objection to massage of the abdomen and electricity is that they are expensive and require much more time than many patients can give to them. Drugs are usually too powerful, and once their action is exhausted are apt to leave the patient more constipated than before. A physician residing in Paris, Dr. Vladimir de Holstein, claims that a satisfactory result may be obtained by administering creosote. This drug should be given pure, and not, as usually is done, in alcoholic solutions or in pills. Seven or eight drops should be given twice daily, after a meal, in a glass of water or any other liquid. If the dose is found not to act it should be

increased. Inasmuch as the patient may complain at first of the burning caused by the creosote, it is often well to begin by a smaller dose, say one drop daily, increasing daily one drop, until the desired result is obtained. Not only is constipation done away with, but the appetite increases, and the general condition is improved.

This treatment should be continued for several months. Dr. Vladimir de Holstein thinks that creosote does not act as a purgative, but neutralizes some intestinal toxin which causes paresis of the intestinal tube.

In a previous letter I gave an account of the favorable results obtained in China by Dr. Yersin in the treatment of the plague by means of subcutaneous injections of serum. During 1897 the results were not so good. In a communication made to the International Medical Congress at Moscow Dr. Metchnikoff gave some statistics concerning the effects obtained in India at the hospital of Cutch Mandvi. The mortality among 685 patients not treated with serum amounted to 549, or eighty per cent., whereas the mortality among 141 cases treated in Bombay and Cutch Mandvi by means of serum amounted to forty-nine per cent. only. Among 500 persons living in contact with plague-patients and treated with preventive injections, but five cases of plague occurred, of which two were fatal.

The cause of the comparative non-efficacy of the serum during 1897 must be attributed to the weakness of the serum, the horses having been only recently immunized. Most of the serum was preventive in mice only in doses of one-tenth of a cubic centimeter; while some of the serum was so weak that the preventive dose for a mouse was one-fourth and even one-half cubic centimeter.

According to Dr. Roux serum prepared by the intravenous injection of agar cultures is more powerful than serum prepared by means of dead bacilli.

#### *DOSE OF BICHLORIDE OF MERCURY HYPODERMICALLY IN SYPHILIS.*

To the Editors of the THERAPEUTIC GAZETTE.

GENTLEMEN: In the issue of the GAZETTE dated August 16, 1897, there is an article entitled "Sixteen Years' Experience in the Treatment of Syphilis by the Hypodermic Injection of Bichloride of Mercury," which is taken from the *New Orleans Medical and Surgical Journal* for April, 1897.

Throughout the entire article no mention

is made of the strength or preparation of the solution nor of the dose administered at one injection. I am much interested in this method of treatment for that dread disease, and would highly appreciate any information you may be able to give me and the profession in general on these points, which I consider are of vital importance.

I notice that only the closing remarks of Dabney's paper are given, and any information on the solution and dose is purposely omitted. If you can and will furnish me with the requested information, I shall be greatly pleased and under many obligations. Would like to see it in the next issue as well as to hear from you personally on the subject before that time, as I am anxious to give it a trial.

In closing I will say that I have but recently subscribed for the GAZETTE, as well as *Medicine* and *The Medical Age*, also published by William M. Warren, of Detroit, Mich., and am greatly pleased with all of them. The GAZETTE is particularly interesting, inasmuch as it contains so many short and "to the point" articles.

I shall hereafter try never to be without it.

Very cordially yours,

FREDERIC D. LEE, M.D.

428 ELEVENTH AVENUE, MILWAUKEE, WIS.

August 23, 1897.

[Dabney's article is an extremely able plea for the treatment of syphilis hypodermically. He reports seven successful cases. The solution employed was one of bichloride, one grain to the drachm. In the first case fifteen minims of this solution was injected just under the skin below the deltoid of the left arm. The dose was increased up to twenty-one minims. This patient received in all ten injections and was discharged. The strength of solution employed in subsequent cases was the same.

The second case, a boy, received ten injections, beginning with six minims, increasing to eleven minims.

The third case refused treatment because of the pain.

The fourth case was treated hypodermically for several months.

The fifth and sixth cases received ten injections of twenty minims each.

The seventh case, one in which the dermal manifestations were unduly severe, was treated by four daily injections of twenty-five minims, after that thirty minims every three days until ten injections had been given.

### *THERMOTHERAPEIA, OR THE HOT-AIR TREATMENT, AND ITS USES AND POSSIBILITIES.*

BY ELLWOOD R. KIRBY, M.D.,  
Surgeon to St. Mary's Hospital and Visiting Chief to Surgical Out-patient Department St. Agnes Hospital; Instructor in Clinical Surgery in the University of Pennsylvania;

AND

JOSEPH M. O'MALLEY, A.C., M.D.,  
Visiting Chief to the Surgical Out-patient Department St. Agnes Hospital.

The effects of heat upon the human body are, of course, for the most part the opposite of cold. By surrounding the body with a

temperature higher than its own the destruction of the tissues by oxidation is considerably diminished; and many curious facts have been discovered, but with few exceptions these facts still remain to be explained.

For the first knowledge of thermotherapeia the medical profession is indebted to Mr. Urquhart. He found that the treatment was adopted in various parts of the world, and that its use was almost universal in cold and temperate climates, but absent in the tropics. By the people among whom it was found the application of hot air was employed as a luxury and a religion—the religion of physical purity—but not as a remedy against disease. It was left for Urquhart to apply

highly heated air as an agent for the relief of pain and disease, with the most signal benefit.

The capacity of the human body for bearing dry air at a very high temperature is a matter of common observation; we see it in the daily occupation of copper smelters, puddlers, and stokers. In well ventilated rooms a temperature of from  $170^{\circ}$  to  $200^{\circ}$  is not only bearable but absolutely soothing and agreeable.

The essence of the quality of a high temperature is its dryness, and when absolutely dry a temperature of  $400^{\circ}$  has been borne for several minutes. If the air be moist, a temperature of  $130^{\circ}$  or  $140^{\circ}$  will begin to scald. The great value of dry heat we can clearly see by the universal use of the Turkish or Russian baths; but the application of high degrees of dry heat to the entire human body is dangerous at times.

It has been only within the past two years that any attempt has been made in the use of a definite apparatus, by which a high degree of dry heat at a known temperature can be applied to a part of the human body without the dangers of serious or accidental results from the disorganization of tissues. It is a well known fact that heat applied to the human body will relieve pain and also abort many simple inflammatory conditions, but just how this is brought about is rather difficult to explain. It has been determined experimentally that a temperature of  $140^{\circ}$  F. applied to a motor nerve will produce motion in parts supplied from direct irritation, and that a temperature of  $212^{\circ}$  F. is capable of producing the most violent tetanic contractions, which are entirely due to the disorganization of the nerve tissue.

The apparatus used in the following experiments is one constructed by Lentz & Son, of Philadelphia, and is a most admirable one for its simplicity of construction and its price. The actual space required for the machine is  $3 \times 2\frac{1}{2}$  feet, and with chair for the patient the total space is  $5 \times 2\frac{1}{2}$  feet. Two gas-jets are used for ordinary pressure; these will bring up the required temperature of  $300^{\circ}$  to  $400^{\circ}$  F. in from forty-five minutes to one hour. The actual cost of running the apparatus is about two cents per hour. It is entirely portable, its total weight being under forty pounds.

*Technique of Application.*—The temperature of the machine is allowed to reach  $200^{\circ}$  F.; the patient's limb is then carefully but loosely surrounded by a large blanket, special care

being taken to allow a considerable air space between the blanket and toes or fingers, and also that the limb just within the iron rim of the machine be thoroughly protected to prevent burning from the heated metal. The canvas hood is now made tight about the limb. For experimental purposes the pulse, respiration, and temperature were taken before and after applying the heat, and in all joint conditions the circumference of the same was taken before and after. The average treatment should last from forty-five minutes to one hour, and the temperature should be slowly increased until the full limit of the patient, so far as his sensations are concerned, is reached.

The guide in the matter is the sensation of the patient, who at first usually experiences pain in the toes and fingers, but this is not excessive; and when the temperature becomes intolerable to these parts, as noticed by the very sharp, stinging pain, the temperature is quickly reduced  $10^{\circ}$  or  $15^{\circ}$  by opening the valves at the top of the machine or opening the machine door, or a procedure which we are commonly in the habit of adopting, of opening the door of the apparatus and quickly throwing an ordinary towel into the cylinder. This will absorb a certain amount of heat, thus relieving the distressing pain. After this the temperature is gradually allowed to rise again, until the limit of tolerance is reached, and then lowered. Some surgeons have recommended covering the limb with a piece of lint, or with absorbent cotton, and a bandage. This substance is entirely too thin, and does not absorb the perspiration quickly enough, or may be quickly saturated with moisture; hence in quite a few cases very severe scalds have resulted. When the blanket is used, however, no such injury is possible, if the ordinary amount of care be exercised. Another point in favor of the use of a blanket to encase the limb, rather than lint or gauze, is that the limb is thoroughly protected from the canvas covering of the magnesium; for, although the heat cannot go through the magnesium, it is forced directly through the flues of the apparatus in such a manner that the canvas becomes as hot as the surrounding metal and asbestos, and hence might readily scald.

The thermometer should not be pushed down as far as the limit of the metal guard, as this is continuous with the iron of the apparatus; the instrument will register proportionally higher than the true interior tem-

perature actually is. With a temperature of  $380^{\circ}$  as registered by the thermometer the temperature in the exact center of the cylinder will register but  $350^{\circ}$  to  $360^{\circ}$ , while beneath the first fold of the blanket about  $335^{\circ}$  to  $340^{\circ}$ , and directly next the skin but  $230^{\circ}$  to  $250^{\circ}$ ; so we can therefore notice that quite a difference exists between the temperature as registered by the thermometer of the apparatus and the actual heat in direct contact with the skin.

Immediately after the application the limb or part exposed to heat is washed with alcohol and quickly dried, and the patient allowed to follow his usual avocation. The treatment should be applied daily in acute cases; in chronic cases at longer intervals.

After applications the limb or part is extremely red and hyperemic, bathed copiously with perspiration, skin soft and pliable, and pain, if present before, entirely relieved or much improved. In the lower extremities patients often complain of a peculiar numbness of the limb, a fact which is entirely due to the position in sitting; the limb is markedly extended, and simple extension of the sciatic nerve will produce this condition either in or out of the machine, and has nothing to do with the action of heat upon nervous tissues. Often the circumference of the limb was considerably reduced; at times it was unchanged, a condition which no doubt depends upon the presence of subcutaneous edema or effusion. The explanation as to the relief of pain is rather difficult. Ringer has shown that heat impedes or destroys the electrical currents of nerves, whence it may be fairly presumed that when subjected to this influence they are less able to conduct impressions to or from the brain. The action of the heat in such cases is a temporary one. If the case was allowed to rest with one application the patient might be entirely free from pain for several hours, and when it did return the pain would not be quite so severe as before the treatment. If the treatments are continued for any length of time there is a progressive loss of flesh and strength, amounting in one of our cases to seventeen pounds for thirty heatings. This case was one of double hydrops articuli of the knee, the patient refusing operation. He was led to try the hot air by way of an experiment. The result in this case will be given under the list of cases.

The greatest temperature applied at one time was  $400^{\circ}$ , and the lowest  $270^{\circ}$ , the average treatment being about  $320^{\circ}$ .

A short time after the applications have been made we find that there is an elevation of the central temperature, the highest in our list of cases being  $100.1^{\circ}$  and the lowest  $98.7^{\circ}$ . The average increase of temperature was  $1.2^{\circ}$  F. The pulse is at the same time somewhat increased in frequency, the greatest being 120 and the lowest 92, showing an average increase in the pulse-rate of thirty-three beats per minute.

When very high degrees of heat are applied to the human body there is at first a violent vasomotor contraction and an increase of blood-pressure, but when a temperature of  $380^{\circ}$  F. of dry heat is applied there is a vasomotor dilatation, as borne out by the increased action of the sweat glands, the increase of temperature, which is almost always associated with dilatation of the capillaries, and finally by the flushed appearance of the skin. The tracing shown was taken ten minutes after the application of a temperature of  $380^{\circ}$  F. dry heat to a dog, the animal being fully anesthetized.

Sonnenburg says the temperature rapidly rises shortly after the application of heat, and considers this rise of temperature consecutive to the overheating of the blood. It is incontestible that when the cutaneous surface of man or beast is subjected in totality or in a greater part to the action of an intense heat, the entire blood distributed to the periphery not only becomes hotter, but is considerably altered, and the overheated blood which flows back to the central structures must of necessity be followed by an elevation of the central temperature; but there is in animals a considerable difference, which can be easily appreciated when one takes into consideration the size of the subject. We have frequently observed that in those cases in which the superficial fat was well developed there was less immediate relief experienced from pain; and the elevation of the central temperature is less demonstrable than in those subjects whose muscular and fatty layers are particularly thin.

Sonnenburg states that if a burning substance be brought in contact with the cutaneous surface there is primarily an attempt at self-defense on the part of the organism by an immediate vasoconstriction which prevents the blood from flowing through the burned area, and thereby causing internal congestions. In our series of cases we have noticed on the contrary a vasomotor dilatation with its consequent hyperemia and fall of blood-pressure, the rapidity of which de-

depends upon the intensity of, and the duration of the application of, the heat, results which are clearly due to a paralytic exhaustion of the vascular tonicity. The red blood-corpuscles can scarcely pass through the vessel, while on the contrary the venous dilatation is so great that they occupy one-third more space than in their normal state. Milne-Edwards in his work on comparative anatomy has also studied this phenomena: the action of cold produces a contraction of the arterioles and intense heat produces the same effect, while a moderate heat dilates the vessels. Salvioli confirmed these results by actually measuring the diameter of the vessels before and after the application of heat.

We have noticed from a series of microscopical examinations made of the blood by Dr. Geo. A. Muehlick an excess of accumulation of red blood-corpuscles resulting from the action of the high temperature.

During the past nine months we have treated something over 300 cases at St. Agnes Hospital, with a grand total of 910 heatings for all cases, including 157 cases of recent sprains, eight of the shoulder-joint, seven of the elbow, twenty-two of the wrist, eighteen of the knee, fifty-five of the ankle, twenty-four of the thumb, and twenty-three of the fingers, with most excellent results.

In cases of traumatism of the shoulder it was impossible to get the full effects of the heat because of the difficulty experienced in getting the shoulder within the cylinder of

the apparatus; in general, however, applications to the upper extremity are followed by good results. Each case was treated for from forty minutes to one hour, with a general average of five heatings. In none of these cases was any retentive dressing applied, with the exception of the ankle; in all other joints the full limit of heat was applied for forty-five minutes for small joints, as the fingers and thumbs, and one hour for the larger joints. Our best results were obtained in sprained ankles, all of these cases being heated for a full hour, at a temperature ranging from 300° to 380° F. After each application of heat a Coterell dressing was applied, and the patient told to use the joint as much as possible. The majority of the cases were treated daily; some every third day. Usually one application gave perfect ease from pain; in some cases two applications were necessary before the pain was entirely relieved; and in the great majority of cases three applications were necessary to restore perfect function of the joint. In some of our cases the rapidity of cure seemed marvelous.

We have noticed that in subjects with an excessive amount of subcutaneous fat the first application seemed to be followed by an increase of pain and discomfort; this, however, rapidly wears away within a few hours, and the usual relief of pain is then experienced. This we especially noted in a medical *confrère*, and to use his words, the pain and discomfort were greatly increased after the

application of one hour, but within three hours he experienced a most delicious sensation of comfort and freedom from pain; the second application was followed by complete relief of all symptoms, and he was able to walk after the fourth day of treatment, the function of the joint having returned to the normal state. In this case the gentleman weighed something over 220 pounds. Of course in this class of injuries the intense heat prevents the extravasation of blood and the exudation of lymph between the tendon and its sheath, and if blood or lymph be present they are rapidly absorbed.

CASE II.—A strikingly successful case. L. E., aged forty, who after a fall of twenty feet sustained a very severe sprain of his right ankle; was suffering excruciating pain when brought to the hospital. Heat was applied to the limb for one hour, until the full limit of tolerance was reached; limb was removed from the apparatus, a Coterell dressing applied, and the pain was entirely relieved. This process was continued for one hour on three consecutive days, the patient walking out of the clinic on the third day.

CASE III.—Alcoholic; received a severe sprain of ankle two days before admission to hospital. Heat was applied for two hours, through the carelessness of the attendant. Patient was lost sight of for two weeks, at expiration of which time he returned with Coterell dressing intact, stating that he had experienced no pain during the interval, and had been walking on the injured member from the time of the first application.

CASE IV.—W. B., while walking on a coke bank, turned on his ankle with such force that a hole was torn in right side of shoe at the site of the external malleolus. He was taken to the hospital in the ambulance. Heat was applied for one hour, after which a Coterell dressing was applied, and the patient was walking on the third day.

CASE V.—Jenette C. while walking the street slipped on a banana peel and received a severe sprain of left ankle. When brought to the hospital she was suffering intense pain and the joint was greatly swollen. A single application of heat was made and a Coterell dressing applied, and the patient left the hospital immediately, walking on the injured limb.

CASE VI.—Marie M., aged twenty, fell from a bicycle, receiving a sprain of the right ankle. When admitted to the hospital her limb was enormously swollen. Heat was applied for four consecutive days; after the

fourth application a Coterell dressing was applied, and the patient walked home without much effort.

Numerous other cases were treated in like manner, with the same gratifying results. In the great majority of cases pain was relieved in a marvelous manner, and the function of the joint was restored to the normal in all cases after the fourth application. We have experienced the same good results with the treatment of smaller articulating surfaces; the following case serves to illustrate:

CASE VII.—Mrs. C., after a severe fall, in an attempt to save herself threw out her right hand, injuring thumb. Rapid traumatic plastic synovitis followed the injury, with adhesions locking the thumb under the index finger. Unsuccessful attempts had been made on several occasions to relieve the condition. Heat was applied to injured member, at a temperature of  $340^{\circ}$  for one hour, after which the adhesions were forcibly broken up, and patient was enabled to use her thumb freely.

We have not experienced the same uniformly successful results in chronic joint injuries. This is to be explained in part by the fact that in acute injuries the excessive application of heat causes a vasomotor dilatation, thus relieving engorgement of capillaries and in consequence pain. In chronic cases on the other hand, the exudate organizes into a low grade of fibrous connective tissue; there is not the same capillary dilatation, and the same relief from pain is not experienced. We have also observed in simple hydrops cases that the infusion in the majority of cases is rapidly absorbed, although the time required for treatment is considerably longer than in acute conditions. In those cases of sprains showing the peculiar tendency to plastic formations of comparatively recent date, the same good results were obtained as in the acute conditions, but when of very long duration little good resulted from the applications.

These results are decidedly an advancement over the older methods of treatment of sprains. Formerly a sprained ankle required from five to six weeks of active treatment, with serious incapacitation of patient for active duties, and the patient almost invariably suffered pain, discomfort, and swelling of the limb for several months afterwards.

Careful measurements of the joints were made, and a decided diminution in diameter occurred within a period of twenty-four hours afterwards.

In chronic synovial effusions of joints our

experience has been limited to four cases, in one case of hydrops articuli of both knees, for which operation was refused by patient. Thirty applications of heat were applied by way of experiment. Accurate measurements of the circumference of each joint were made, with a marked diminution in the size and effusion. After the thirtieth application there was still some fluid in the joint. In this case we noticed a marked decrease in the weight of the patient, and treatment was discontinued. The remaining three cases were not of such long standing; while they were benefited in many respects by the treatment, yet the results were not so gratifying as in the treatment of the acute cases. In these three cases the joint was fixed in the interval. Treatment was discontinued after ten applications, and the usual treatment for these conditions was carried out.

We have met with unvarying and remarkable success in the treatment of acute synovial effusions, the patient experiencing a rapid relief from pain and progressive diminution of the effusion.

Our experiences in these cases coincide in every way with the experience of Professor H. C. Wood in his article, in which he says: "The application of dry heat is of very little value in chronic joint conditions."

*Tuberculosis.*—We have been very much interested in the application of hot air to the treatment of tubercular arthritic affections. We have been unable to secure sufficient material as a basis for positive statements; we thought that we might in some way be enabled by the application of a very high temperature to destroy the tubercle bacillus. It is a conceded point that the tubercle bacillus is easily affected by comparatively low temperatures, and its activity destroyed at 160° F. Taking for granted a child with tubercular arthritis, the joint of course very small, if the temperature of the apparatus be raised to 380° F. or an interior temperature of 350°, it seemed to us possible that with a temperature of 230° in actual contact with the skin sufficient heat might be brought to all parts of the joint by continuity and contiguity of tissue, and that we might thus destroy the organism. Unfortunately we were only able to experiment upon one suitable case; this was one of tubercular skin infection in a veterinary surgeon of Downingtown. Sections of the ulcer were made by Dr. Raven, of the University of Pennsylvania, and tubercle bacilli were found. Five applications of from 380° to 390° were made

at intervals during six weeks. The ulcer promptly cicatrized, all induration disappeared, and the Doctor writes that he has had no further trouble for the past four months, and is evidently cured.

We have as yet not been able to experiment with other local non-pyogenic infections. We think, however, if the heat could be applied that its curative effects upon lupus would be quickly demonstrable. Of course, it is needless to say that sufficient heat could not be applied to the skin for the purpose of destroying pyogenic organisms, as these microbes are only killed by such temperatures as would entirely disorganize the human tissues.

In acute rheumatic cases we have met with gratifying results in the use of dry heat. The patient experiences an immediate sense of relief from pain, and a marked diminution in the swelling of the part. In one case we have in mind the usual treatment had been thoroughly tested for two weeks without result; the pain was very severe, and patient experienced her first relief from pain after the use of the apparatus. Six other acute cases seemed to be completely cured, while the remaining eight were greatly improved. Of the chronic cases we treated thirty; all experienced a relief from pain, but there was no permanent improvement manifested. This seems to be the experience of all observers.

*Rheumatoid Arthritis.*—Our experience with the treatment of rheumatoid arthritis has been disappointing. We experimented upon one man of twenty-eight years in whom nearly all the joints of the body were involved; the patient was unable to walk without the aid of crutches. The case was one of fifteen years' duration, and all forms of treatment known had been tried unsuccessfully. Accurate measurements were made of the joints before and after treatment; pulse, respiration and temperature were carefully noted. Both lower extremities were exposed to a temperature from 300° to 320° F., each limb being permitted to remain in the apparatus for a period of one hour. We were led to expect brilliant results after the second heating, the patient being able to walk out of the clinic without the aid of his crutches, and his general condition seemed improved. After about ten days, however, he became anemic, lost eleven pounds, and was forced to discontinue treatment, and since then the patient's condition has been much worse than before the treatment was begun. From the experience of Professor Wood it would seem

that the hot-air treatment is absolutely contraindicated in rheumatoid arthritis, and in fact in cases of simple rheumatism with any bony exostoses about the joints; and little or no good may be expected from the treatment of these cases.

*Leg Ulcers.*—Nine cases of the ordinary callous ulcer of the leg were subjected to the application of heat. Assuming that the circulation is increased in the part, we hoped by the resulting lymphatic stimulation to obtain granulation tissue reaction, and thus by favoring a better metabolic exchange in the tissues to hasten the cure of these otherwise obstinate conditions. These cases were somewhat improved, and in several the ulcers rapidly took on a healthy granular appearance. The callous area is rapidly softened and the ulcers look clean, and the granulations when formed have the normal healthy appearance. We concluded that this will be an excellent preliminary procedure in the treatment of these conditions.

*Elephantiasis.*—In the one case of elephantiasis subjected to this treatment we had hoped to stimulate the lymphatic system, and thus bring about a certain amount of improvement. Patient discontinued treatment voluntarily after the third application, and no definite conclusions could be drawn.

*Fractures.*—Thirty fractures, including seventeen Colles, six of tibia and fibula, seven of fractures of the lower end of the humerus, were subjected to the hot air after the dressings had been removed. It is usually stated in text-books that the average cure of a broken bone requires about six to eight weeks; this only includes the time the fracture is uniting, but many weeks and sometimes months are required to limber up joints and tendons before the normal function is restored. Colles's fracture is of very frequent occurrence, and it is well known the disability that follows this fracture often extends over a very long period. We hoped the hot air would so soften the adhesions that a rapid absorption would speedily follow and the function of the joint be rapidly restored. We were right in this surmise. In every case after the splint was removed the part was subjected to heat to the point of tolerance, which we observed to be considerably below the usual limit, which is in all probability due to the defective nutrition of the part, and the excessive amount of engorgement of the lymph channels.

In every case the function of the limb was rapidly restored, edema and swelling rapidly

disappeared, and the patient was enabled to follow his usual avocation much earlier than in cases treated by massage and electricity. Massage combined with the hot air treatment might still further hasten a cure, but this procedure was eliminated from our cases for experimental purposes only.

*Dislocations.*—We treated a number of dislocations of various joints and met with uniformly good results, in causing the absorption of the lymphatic adhesions between the articular surfaces and a rapid disappearance of the swelling. Heat was applied when the dressing was removed and the capsular ligament supposed to be entirely healed.

*Tenosynovitis.*—Eight cases of tenosynovitis were treated; all were of traumatic origin, seven being about the wrist-joint and one at the elbow; four were acute and four chronic. Of the acute cases all were promptly relieved by four treatments; splints were applied in these cases after the application of the heat. In the chronic cases improvement was slower; the pain was promptly relieved, but crepitation could be felt for some time afterward. After seven heatings patients were cured and able to return to work. The heat seemed to be of special value in these cases, and when the exudate about the tendon was not excessive it was rapidly absorbed. In those cases in which the exudation was excessive the use of an antiseptic seton was combined; the improvement was rapid, and permanent cure soon resulted.

Assuming that the theory in regard to the destruction of the tubercle bacillus by the application of a high degree of heat is correct, we think that the treatment should be followed by the most brilliant results in cases of tubercular tenosynovitis.

*Ankylosis.*—Seven cases were treated—two of elbow, three of knee, and two of shoulder. All these cases were of traumatic origin and of long duration. As many as twelve or fifteen applications were required in each case before permanent improvement was noticeable, but in all the final results, with the exception of one elbow, the range of motion was increased to a remarkable degree. The elbow case discontinued treatment of its own accord.

In conclusion, we believe that the application of dry heat will find its greatest use in those cases of acute origin, such as sprains, tendinous inflammations, acute muscular strains, acute rheumatic conditions, and as an after-treatment of fractures and dislocations, to promote and aid the elimination

of effete substances through the skin, by sweating and through the lymph channels, increasing the blood-supply and thereby the nutrition of the part. We think it is absolutely contraindicated in cases of rheumatoid arthritis, and of but little value in chronic rheumatic affections. We believe with Dr. Wood that the general sweating has something to do with the relief of these cases. Little experimental work in the line of tuberculosis has been done, but the brilliant results obtained in our one case encourage one to further investigate this matter. We are now doing some experimental work with the view of ascertaining whether the application of a high degree of dry heat will in any way facilitate the penetrating power of ointments. One can readily see the boon to syphilographers if the permeability of inunctions be furthered, thus enabling one to rapidly saturate the system with physiological doses of mercury.

Our experiments also have led us to believe that if an apparatus could be constructed enabling one to adapt this method of dry heat in pulmonic congestions, the vasomotor dilatation ensuing, literally bleeding one into his own arteries, many distressing and dangerous symptoms, as cyanosis and dyspnea, might be relieved or mitigated. It seems to us that this subject is well worth further investigation.

---

#### THE POST-OPERATIVE TREATMENT OF SURGICAL CASES.

---

BY THOMAS LEIDY RHODES, M.D.,  
Assistant in the Surgical Clinic, Jefferson Medical College  
Hospital.

(Continued from page 664.)

**Vomiting.**—One of the most troublesome symptoms with which we have to deal after anesthetization is vomiting, and it is necessary that the patient should be constantly watched until consciousness is fully restored and the sickness at the stomach has passed away. Very few patients come out of the anesthesia without experiencing some degree of gastric disturbance, a severe retching representing the height of the distress in some instances, while in others a continual ejection of the contents of the stomach may be but a prodrome of a most alarming state.

As soon as the patient is arranged properly in bed means should be taken to avert this unpleasant sequel to the anesthetic. The patient, as a rule, will do better by lying on his back, pillows being laid aside, and the

head and shoulders resting low, so that the ether vapor may pass from him more readily. A towel is spread about his head and shoulders and a basin is within easy reach to catch the vomitus, if necessary. It is well, however, not to let the patient see the basin while he is regaining consciousness, as the sight of it may be suggestive enough to provoke an uncontrollable nausea. If the gastric disturbance is nothing more than a severe retching, and this condition has resulted from the administration of the anesthetic *per se* and is not due to the accumulation of a large quantity of ether-soaked mucus in the stomach, it may be checked by a simple maneuver which the writer has frequently used with success. The head is thrown backward and traction is made strongly upwards with the hands, on each side of the lower jaw. Vomiting does not occur unless there is fixation of the diaphragm and closure of the glottis, and by making traction upward on the lower jaw the hyoid bone is raised and with it the epiglottis. The reflex action of this maneuver will generally control a slight nausea and retching. While this is being done the patient's face should be bathed with cold water to aid in restoring consciousness quickly. On the other hand, if vomiting comes on, as it usually does in patients in whom there has been profuse bronchorrhea during the administration of the anesthetic, it is the direct result of the irritant action of the ether-soaked mucus on the gastric mucous membrane, and it is well to let the patient get rid of this mucus rather than to retain it and let it be the cause of continual nausea during the first twenty-four hours. In these cases Hearn advises the administration of a half glassful of warm water to induce vomiting to rid the stomach of its contained mucus at once. The moment he starts to vomit, the patient's head is turned and held to one side, he is restrained from rising, and the basin is held alongside his head. If he has not recovered consciousness sufficiently to understand intelligently the directions of the attendant, his mouth is wiped out frequently with a towel so that the retained mucus or particles of food will not pass the chink of the glottis and enter the trachea, a source of great danger from vomiting and one to be carefully guarded against. The local anesthesia of the parts interferes with the usual guarding of the passageway to the lungs, and the patient may become asphyxiated from particles of food lodging in the trachea

or bronchi, providing the necessary precautions have not been taken to guard against this occurrence by a previous course of dieting and by withholding food for at least five hours before operation.

There is one surgical affection, however, which may be mentioned here, where even a course of dieting and the withholding of food for several hours before operation is not a sufficient prophylactic against this occurrence. In stenosis of the pylorus the ingested food is improperly cared for, owing to the associated changes which occur in the viscus, and the stomach constantly contains a quantity of undigested material and curdled milk which cannot at once pass the stricture at the pyloric end. These particles of food it has been shown lie there for days at a time, and it will be readily seen that the usual precautions before anesthesia will not relieve this condition. Dr. Hearn has put it down as a cardinal rule that before operating for stricture of the pylorus the stomach must first be thoroughly emptied by irrigation, so as to avoid the later dangers from ether vomiting.

A case illustrating this point was recently seen in one of the city hospitals, where a noted surgeon proposed to do an operation for stricture of the pylorus. The abdomen was opened, but the case was found to be inoperable, and the exploratory incision was closed. On being lifted from the table the patient retched a great deal, he became cyanosed, and in spite of efforts to revive him expired shortly after. The post-mortem disclosed the bronchi filled with particles of undigested food which had regurgitated into the trachea during the efforts at vomiting. Yet this patient had not received food for some days.

If the attendant knows that his patient's stomach contains no food or curdled milk, he has nothing to fear from this source, for should some of the vomitus enter the patient's trachea, being nothing but a thin, frothy mucus, it can do no damage even to the mucous surface.

The principal harm lies in the fact that the vomiting, if long continued, causes much cardiac depression, and that it may lead to a misplacement of the dressings and thus interfere with early wound repair; and if it continues beyond several hours and after the patient has fully regained consciousness, means must be taken to check it. A mustard plaster applied to the epigastrium often suffices, with an ice-bag resting under the nape of the neck. At the same time the expedient

of Mackenrodt may be carried out by covering the patient's face with a cloth saturated with vinegar, so that all the air inhaled contains vinegar vapor. No food or fluids should be administered internally while these measures are being carried out. At times, however, it may not yield to this simple treatment, and various internal remedies must be resorted to. Twenty drops of a five-per-cent. solution of eucaine hydrochlorate is given by the mouth in a teaspoonful of very hot water, and repeated every fifteen minutes until four or five doses have been given. This failing to allay the nausea, the popular prescription of Hearn may be tried:

℞ Spiritus chloroformi, 8 minims;  
Acetum opii, 3 minims;  
Mucilage acaciae,  
Aqua, aa q. s. 1 drachm.

Repeated every hour; or the writer's formula:

℞ Hydrarg. chlor. mite., 1-10 grain;  
Cerium oxalatis, 2 grains;  
Codeia sulphatis, 1-5 grain.

Ft. Charta.

Give at intervals of half an hour until four or five powders have been administered. This not only prevents any increase in the amount of mucus collected in the stomach by checking secretion, but also acts as a gastric sedative.

Should the vomiting continue throughout the day and show no signs of abating after the several remedies mentioned have been tried, we can resort to an exceptionally valuable measure in its therapeutics in the way of lavage, a method first advocated by Kussmaul, but greatly simplified in its application since its introduction. The stomach is irrigated with a pint or more of warm boric acid solution (five grains to the ounce) and by a process of siphonage is emptied at once of all the remaining ether and mucus, and bile that has regurgitated through the pylorus from the continued efforts at vomiting. The arrangement that is most commonly used for this purpose, and which is so simple in its construction that it can be made ready at a moment's notice, consists of a glass funnel of a capacity of about 300 to 500 cubic centimeters, attached to a piece of soft-rubber tubing about a yard in length and connected with a soft-rubber stomach tube having several openings at its lower end. The tube of Ewald is the preferable one. The patient's head is raised on a pillow, for when the head is slightly bent forward this position favors the entrance of the tube into the esophagus. The stomach tube, having first been im-

mersed in a pitcher of warm water, is inserted into the open mouth of the patient by the attendant, and is passed into the pharynx. It is unnecessary for the attendant to insert his finger into the mouth of the patient during this procedure. The patient is now told to breathe deeply and to swallow once or twice, and the tube is pushed down rapidly, with the right hand, into the stomach, a distance of forty-four to forty-five centimeters. By raising the funnel several feet above the level of the patient's head, and filling it with the warm boric acid solution and allowing the fluid to run into the stomach, then lowering the funnel so as to permit the fluid to run out again, the stomach may be filled and emptied until the fluid returns clear and the viscus is thoroughly washed out. In case the outflow of the fluid is suddenly arrested by particles of food obstructing the openings in the stomach end of the tube, a small quantity of solution is poured into the funnel again and the siphonage repeated. When the fluid returns clear the stomach tube is withdrawn quickly. While removing the tube it is pinched shut at its free end to avoid the passage into the esophagus or pharynx of some of the mucus, etc., contained within the tube. This method will be found highly effectual in the management of obstinate cases. Bonnefin's method of faradization over the pneumogastric nerve has in our hands yielded no apparent good results.

If the foregoing treatment proves ineffectual and the vomiting continues unabated for two days after the operation, it is generally a prodrome of peritonitis, and this complication should be suspected, especially after abdominal operations. If the vomiting is of a stercoraceous character, intestinal obstruction exists. Each of these grave conditions must be met with a correspondingly prompt and decisive surgical interference.

*Thirst.*—If the anesthesia has been prolonged for an unusual length of time, and if its administration has been followed by copious vomiting, there occurs as a sequel an inordinate and distressing thirst. This craving for water is often so great that patients have risen from their beds several hours after serious operations, the nurse being otherwise occupied, and have drained the glass of the neighboring patient in the hospital ward. This craving is especially severe after operations in which the peritoneal cavity has been opened and the abdominal viscera handled, but the reason for this fact has not yet been definitely explained.

To withhold fluid in a limited amount from cases in which there is marked thirst after operations entails an amount of suffering and restlessness that may interfere materially with the patient's ultimate recovery. The mandatory abstinence from drink observed by some surgeons with their patients for the first day, or even the first forty-eight hours, is unnecessary and unwise. Operative cases after anesthesia should not be allowed to suffer cruelly from thirst; but at the same time it is equally unwise to answer every appeal of the patient for water. The existence of shock, the effects of the constant emesis, and the direct action of the ether-soaked mucus on the gastric mucous membrane, leave the stomach inert and render absorption inactive, and it is useless and even harmful to distend the stomach with copious draughts of water to the detriment of the already enfeebled powers of digestion. Such a course simply results in greater discomfort and the vomiting is renewed. By judicious management the patient's thirst can be alleviated without causing him any additional discomfort or nausea and without encroaching upon the functional capacities of the stomach from the ingestion of large quantities of fluid.

The prophylactic measures advocated by Humisten in the management of this troublesome symptom are of the utmost value. Patients are taught to drink half a pint to a pint of water every four hours several days prior to an operation of gravity, and particularly before an abdominal section is to be performed, to supply to the tissues the loss by catharsis and to anticipate the usual sequel of the anesthetic. The water should preferably be given hot, and about two quarts should be administered during each twenty-four hours. This preliminary treatment has the power to allay to a great extent the thirst which usually follows operation, and has the additional advantage of keeping the mucous membranes moist, and flushing the kidneys.

Next in importance is the method of Kelly, who counteracts the disagreeable subsequent thirst by performing enteroclysis at the completion of his major gynecological operations. This treatment is especially effective after operations in which hemorrhage has been profuse and the tissues have been drained abundantly of their normal supply of fluid. After the completion of the original operation, and while the patient is still on the operating table, his hips are elevated on pillows and a quart of warm saline solution

is injected high up into the bowel through a large-sized soft-rubber catheter. In order that this injection be effective it is necessary that the lower bowel should have been previously emptied and cleansed by catharsis and repeated enemata. It is also essential to success in carrying out this procedure that the anesthesia be continued during the performance of enteroclysis, in order that the bowel will retain the injected fluid.

When consciousness has returned the tongue should be frequently moistened with a weak mixture of tincture of myrrh, a teaspoonful to half a glassful of water, or a weak solution of borax, or a solution of glycerin one drachm, in alcohol and water, each an ounce; a piece of linen being saturated with one of the several solutions, the patient is told to hold this in his mouth for several minutes at a time.

When all efforts at vomiting have passed away, which in the general run of cases is in from four to five hours after operation, the patient is allowed to sip slowly a cupful of weak tea, without sweetening, or hot water, or toast water, according to his liking. This is administered to him with a spoon by the attendant, the patient lying quietly in a comfortable position. Under no circumstances should he be allowed to rise or drink the fluid down in gulps. The stomach must be coaxed back to its normal state by gentle and persuasive means. After sipping the hot tea or water, as the case may be, the patient usually drops into a gentle sleep, lasting about a half hour, from which he awakes feeling somewhat refreshed, but still annoyed with the feeling of thirst. At this stage several hypodermics of distilled water have been found useful to control the annoying symptom. If the stomach is completely settled, finely divided ice and champagne, or if the latter is not obtainable, finely divided ice alone, may be admissible, taken in small quantities, as was the tea. This will be grateful to the mouth and will relieve thirst temporarily, but it should be given sparingly, a teaspoonful not oftener than once every half hour. The ice is pulverized by placing a small lump in a clean towel and striking it against some solid object. The practise of placing a bowl of cracked ice alongside the patient's bed and allowing him to help himself unreservedly is to be condemned. The gaseous distention and renewed nausea which such action brings about are harder to combat than the original thirst.

If thirst is an after-effect of profuse hem-

orrhage which occurred at the time of operation, where the tissues have been drained of an amount of fluid necessary for them to functionate properly, it will be allayed by the same means used to combat the resulting shock as set forth under this heading, namely, by hypodermoclysis or by saline transfusion.

Should the stomach continue to be rebellious for any unusual length of time, enteroclysis must be resorted to, to relieve the thirst as well as other symptoms; a pint of normal salt solution being injected by means of a fountain syringe and rubber tube high up into the large bowel; or, if necessary, stimulants may be combined with the enema and an ounce of brandy or beef-jelly added to tepid water, from four to twenty ounces, passing into the bowel in the same way.

Later in the course of the treatment the patient may partake freely of water, or other beverages may be more grateful and may be substituted, as Apollinaris, seltzer, weak lemonade, weak iced tea with lemon-juice, barley water, or water commingled with jelly. At this stage of the convalescence the fancies of the patient and the experience and judgment of the attendant will furnish a list of beverages whose worthy attributes will not exist alone in its variety.

[To be continued.]

#### STIMULATION OF THE GASTRIC MUCOUS MEMBRANE TO AID IN THE ABSORPTION OF IMPORTANT DRUGS.\*

BY H. A. HARE, M.D.

Professor of Therapeutics in the Jefferson Medical College of Philadelphia.

I have already called attention in an earlier article to the importance of studying the rapidity of absorption and elimination of drugs in connection with their general physiological effects and their dosage.

In certain states of profound vital depression the gastric mucous membrane does not carry on its functions of absorption as it does in health, and as a result we recognize the fact that the use of a drug by the mouth will probably produce no effect because it will lie unaffected in the stomach for hours. Thus in surgical shock or in advanced alcoholic coma it is not by any means rare to find that repeated large doses of drugs have been

\* A paper presented to the Section on Medicine of the College of Physicians of Philadelphia, March 15, 1897.

given with no result for the time being, but as the patient recovers and absorption is renewed the greater part of the combined doses is absorbed at once and the patient is more or less poisoned by the aggregated medicinal doses which he has received. While it is true that patients in this condition if skilfully treated rarely meet with this accident, I believe that in many other instances where the state is less grave the slow absorption of the medicines given is not considered; that the physician is content to give the medicine and then to regard it as physiologically active without considering the possibility of gastric torpor. In some chronic conditions the slow absorption of a remedy is not disadvantageous, but in acute cases its rapid absorption may be of vital importance. It therefore occurred to me that it might be possible to combine with a remedy another substance not possessed of general physiological action, but capable of stimulating the gastric mucous membrane so that it would have its absorption functions increased. It is well known, of course, that iodide of potassium when absorbed is speedily eliminated by the salivary glands, probably in the form of iodide of sodium. Different investigators have studied the rapidity of this elimination and have found that it usually begins in from ten to fifteen minutes, or a little longer, and lasts over many hours. The iodine can be tested for in the saliva by means of starch paper and fuming nitric acid, which will set free the iodine so that the iodine-starch test can be made. Another method of testing the rapidity of absorption would be by the administration of rhubarb and developing a red color in the urine by the addition of liquor potassa, but as the test should be made every few minutes it is much easier to use salivary secretion as a testing medium.

The methods used were as follows:

Cachets containing three grains each of iodide of potassium were given to four patients in the wards of the Jefferson Medical College Hospital, none of whom were suffering from any known gastric lesion or functional disturbance, and convalescent. In other words, the stomach of each was in a condition equal to that met with in the ordinary patient. After the lapse of a few minutes the saliva of each was tested with starch and  $\text{HNO}_3$  every two minutes until the reaction for iodine was obtained. It was found that the reaction was obtained at the following times:

In the case of the patient G. D. the iodine test was obtained in twenty-nine minutes.

In the case of the patient B. it appeared in thirty-five minutes.

In the case of the patient L. it appeared in nineteen minutes.

In the case of the patient McD. it appeared in twenty-seven minutes.

The delay in the appearance of the iodine in the saliva over the delay usually met with is due to the time required for the cachet to be dissolved and set free the iodide of potassium in the stomach. The use of the cachet was, however, necessary in order that the drug might be given in a soluble form and yet not remain in the mouth even as a trace.

The same patients several days later, after all trace of iodine had disappeared from the saliva, received a second set of cachets, in each of which was placed not only three grains of potassium iodide but in addition one grain of powdered capsicum, and the results reached were as follows:

The patient G. D. gave the iodine reaction in nineteen minutes, or ten minutes sooner than before.

The patient B. gave it in twenty-nine minutes, or six minutes earlier.

The patient L. gave it in nine minutes, or ten minutes earlier than before.

The patient McD. gave it in forty-five minutes, or eighteen minutes later than before.

Whether this last result depends upon the unknown prior ingestion of food or drink could not be discovered.

In order to make a control experiment with this case another test was made several days later, after all iodine had disappeared from the saliva, with the result that the test was developed in seventeen minutes, a gain of ten minutes over the test without the capsicum.

It is evident, therefore, that the use of a gastric stimulant aids very materially in the absorption of the other drug, and the moral would seem to be that whenever it is possible it is well to combine with a drug some gastric stimulant to aid in its absorption. This is particularly necessary if there is any reason to believe that the stomach is in a state of atony, as evidenced by a relaxed tongue and a history of excessive eating or drinking or chronic catarrh.

Iodide of potassium is a drug which lends itself readily to such experiments, but it is probable that other remedies could be studied almost equally readily.

*THE DIPHTHERIA BACILLUS IN THE  
TREATMENT AND SEQUESTRA-  
TION OF CASES OF DIPH-  
THERIA.*

BY ROBT. L. PITFIELD, M.D.,  
Philadelphia.

There are certain biological characteristics of the diphtheria bacillus, all of which should be familiar to every clinician if he would intelligently conduct the management of a case of diphtheria.

The life history of the organism within and without the body, the thermal death point, the action of desiccation, moisture, light, and antiseptics upon it, and lastly and most important, its pathogenic properties—all actively concern the clinical conduct of a case.

The native home of the diphtheria bacillus is the mucous surface of the human fauces; the various warm, moist, dark crypts secreting alkaline mucus form a combination of conditions exactly suited to the life and growth of the bacillus. Outside of the throat it rarely lives for any length of time, leading no saprophytic existence as do many other pathogenic microbes, such as the bacilli of cholera, typhoid, and tetanus.

Cases of diphtheria in cats, chickens, and other lower animals have been occasionally reported, but they are rare, and diphtheria in these animals figures very little in the etiology of the disease in human beings. The bacillus does not long resist the action of sunlight, and diffused daylight very probably attenuates it. It resists desiccation from three to four weeks—that is, in the dark or places unexposed to sunlight, as pockets of clothing, in books, and the meshes of bed-linen, etc. Moisture preserves its vitality, since the latter condition is essential to its multiplication.

Since there are no spores formed by the bacillus, it is quickly and readily killed by heat; Welch and Abbott found that ten minutes' exposure to a temperature of 136° F. (or 58° C.) was sufficient to prevent the future growth of the germ, and scalding water quickly kills it, moist heat being especially inimical to the protoplasm of all bacteria. Washing and ironing linen, especially if the soap is strong and the ironing done with a hot iron before the articles are well dried, probably destroys the vitality of all bacilli that contaminate it. All bed-linen and clothing, however, should be boiled before washing, and finally immersed in a weak bichloride of mercury solution before drying.

The bacillus is never found in drinking-water and very probably is not associated with sewer-gas, since it does not rise from a moist surface and is not carried by the air circulating in the room nor in the air respired; but it may be expelled by coughing. The air coming from the throat of a diphtheritic patient is sterile except when forcibly expelled; here bits of membrane, food, or drops of saliva are caught up and ejected.

While the air of the sick-room may contain bacilli they are few in numbers, but they have been found on the sheets, pillow-cases, on the furniture, shoes and clothing of nurses, and on the hands and in the hair of the patient; also on dishes, napkins, and night-dresses.

The most important biological features of the organism are its uniform tendency to secrete toxin when it finds lodgment in the throat, and to form pseudo-membranes by coagulation necrosis, the latter being due to the toxin; and this is the sum and substance of the pathology of diphtheria. Cloudy swelling in the muscles of the heart and substance of the kidneys, with fragmentation of the nuclei of cells, and degeneration of the nerve trunks, are but ultimate manifestations of the toxicity of the ptomaine.

There is but one way to meet the action of the toxin, and that is with the antitoxin; this should be given as early after infection as possible. The infecting organisms and false membrane should also be destroyed and removed, and for this purpose Loeffler's mixture may be used, also Monsell's solution and ten-per-cent. formalin, with sprays of peroxide of hydrogen between the applications of either of the above.

Since sunlight speedily kills the bacillus a sunny room should be chosen for the sick-chamber. During the disease ten-per-cent. solutions of trikresol or formalin should be used to disinfect all discharges from the throat and nose; or these should be caught on absorbent cotton or rags and burned, and the hands and face sponged with a five-per-cent. solution of formalin. A sheet saturated in ten-per-cent. formalin solution and hung over the door and kept wet, not only prevents the few floating bacilli from escaping, but reminds those persons without not to enter and those within not to leave until the hands are disinfected. All dishes should be scalded before they are removed from the sick-room, and then carefully washed separately in hot water with plenty of yellow soap. Fecal discharges are not very con-

tagious, possibly not at all so; however, bichloride solution may be used in the vesicles.

Laryngeal cases demand especial attention and often require intubation or tracheotomy; here evaporating water to which a little lime or ammonia muriate has been added renders the air moister and favors respiration.

The convalescent patient should be quarantined until a careful bacteriological examination proves the absence of bacilli from his throat and from that of his nurse. This is the most essential feature of the whole preventive management of a threatened diphtheria epidemic. Various measures may be employed to hasten the elimination and destruction of the bacteria. Thus, formalin in five-per-cent. solutions hourly may be used as a gargle when the patient is awake; astringent applications should be avoided, since they occlude the openings of the tonsillar crypts and prevent free access of the antiseptics. The woodwork of the room should be carefully scrubbed with bichloride solution, the walls rubbed with bread previously soaked in formalin, and the whole room atmosphere should be saturated with formalin-gas generated from formaldehyde solution; many contradictory reports as to the use of formalin generators that generate the gas from wood alcohol render the use of such appliances of but dubious efficacy. A final washing of the patient in carbolized water or formalin water should complete the hygienic toilet of the case.

One feature must not be lost sight of, and that is the immediate immunization of all children who have been exposed to infection; and for this purpose 500 to 800 antitoxic units in as little serum as possible should at once be injected. While the bacilli may infect the throat of those immunized there is no danger of a virulent form of diphtheria developing. Adults with weak throats, especially those having enlarged tonsils, also should be immunized.

---

#### REPORT OF A CASE OF TETANUS.

---

BY DR. G. O. COFFIN,  
City Physician, Kansas City, Mo.

---

On July 19, 1897, Chas. N., a large and powerfully built colored man, was received into "D" ward of the Kansas City Municipal Hospital at 12.15 P.M. He was an employee

of Swift's Packing House and cut his hand on a piece of bone ten days previously. On admission the wound was still fresh; and there was an ulcer on the shin of right leg from being struck by a car five weeks before.

Six days previous to admission spasms came on, and patient went to bed at his boarding-house. He had tonic convulsions about every one and a half minutes; could open his jaws one inch; the muscles of the entire body were rigid; the mind was clear; there was pain in back; the bowels were constipated; the urine slight; the abdomen full and tense. Temperature at one o'clock 104° F., pulse 120, respiration 16. He swallowed with difficulty, and exhibited abdominal breathing. He urinated at 4.30 P.M., passing a small amount, highly colored.

I gave fifteen cubic centimeters antitetanic serum (Parke, Davis & Co.) at 5 P.M.; also by the mouth a cup of milk. At 11 P.M. another fifteen cubic centimeter injection of the serum; hypodermic of morphine sulphate one-half grain every three hours during the night. Temperature at 6 P.M. 105½° F., pulse 118, respiration 20.

July 20, at 6 A.M., temperature was 103° F., pulse 128, respiration 24. Injection of fifteen cubic centimeters antitetanic serum at 6.30 A.M.; morphine sulphate one-half grain. Seemed better this morning; urinated during the night; bowels had not moved; spasms lighter and less frequent. Diet, egg and milk. Fifteen cubic centimeters serum at 2 P.M.; temperature at that time 103° F. Breathed more freely with his chest muscles, which were less rigid. Gave usual nourishment at supper time. Temperature at 6 P.M. was 103½° F., pulse 126, respiration 26.

July 21. Morphine was injected at midnight, at 2 and 3 A.M.; serum at 2 A.M. Temperature at 6 A.M. 103½° F., pulse 116, respiration 18. Urinated at 8 A.M., scanty and high colored; bowels constipated; spasms slightly harder and oftener. Took egg and milk. Commenced giving chloral hydrate ten grains and soda bromide ten grains every three hours; spasms seemed to be more severe between the hours of 6 P.M. and midnight. Serum injection at 3 P.M. Temperature at 6 P.M. 104°, pulse 120, respiration 18.

July 22, at 6 A.M., temperature was 103½° F., pulse 108, respiration 18. Felt better; spasms as on previous day, but none while asleep. Diet, milk and eggs. Sphincter ani more relaxed. Swallowed more easily. Had no severe spasms during the night. Slept

more during the day than at first. Serum at 10.15 A.M. At 6 P.M. temperature was 103° F., pulse 98, respiration 18; urinated. Half a grain morphine and fifteen cubic centimeters anti-toxin injected at 10 P.M. Castor oil and glycerin *per os* were given at 11 P.M. Patient rested well.

July 23, at 6 A.M., temperature was 102½° F., pulse 96, respiration 16. Urinated more freely; spasms lighter and less often. Serum at 1 P.M.; enema of water and soap at 3 P.M., removing large amount of feces and mucus. At 6 P.M. temperature was 101½° F., pulse 94, respiration 18. Diet, milk and egg.

July 24. Bowels moved at short intervals during the night. Serum at 2.45 A.M., and milk during the night. Temperature at 6 A.M. 102½° F., pulse 104, respiration 20; gave morphine sulphate solution four drachms (half

July 27. Temperature slowly coming down; to-day it was no higher than 99½° F. Gave oleum ricinus. Began to feed him solid food in good quantities; he could not get his jaws open far enough to eat meat; appetite growing.

July 28. Temperature stayed at 99½° F. all day; pulse 90, respiration 26. Decidedly better; ate anything which did not require much mastication. Bowels did not move; spasms further apart and lighter.

July 29. Temperature 99½° F., pulse 90, respiration 24. Ate an enormous breakfast. Began to turn his neck to either side; could raise arms to head, and could flex his legs unassisted; spasms about ceased.

July 30. Temperature 99° F., pulse 94, respiration 24. Bowels moved freely; suffered some from the heat; gaining strength;

grain morphine sulphate) at 10 A.M.; serum at 12.30 P.M. Urinated freely; jaws open same amount as last few days; spasms about the same this morning, but lighter after dinner. At 6 P.M. temperature was 102½° F., pulse 100, respiration 18.

July 25, at 6 A.M., temperature was 101½° F., pulse 90, respiration 24. Bowels did not move during the night. Attempts to open jaws caused slight spasms; opened about half an inch. Serum at 11.30 A.M. Appetite good; arms not so rigid as the legs; profuse perspiration. Temperature at 6 P.M. 100½° F., pulse 96, respiration 30.

July 26. Serum was injected at 1 A.M. At 6 A.M. temperature was 99½° F., pulse 90, respiration 26. Spasms irregular, but less in frequency; very little trouble in deglutition; slight risus sardonicus, but marked opisthotonos, and pain in chest muscles. Serum injected at 8.30 P.M. At 6 P.M. temperature same as morning.

his masseters had not relaxed much, but his other muscles were in better condition. Could raise and lower his head.

July 31, at 6 A.M., temperature was 99½° F., pulse 94, respiration 24. At 6 P.M., temperature 100½° F., pulse 100, respiration 24. Spasms about one every forty minutes while awake, but they were irregular.

August 1, at 6 A.M., temperature was 99° F., pulse 94, respiration 24; 6 P.M., temperature 99½° F., pulse 94, respiration 24. Sat up for the first time to-day. Spasms no more severe than when a person stretches; little pain and no spasm on touching the abdomen or on awakening him.

August 2. Could use his jaws for masticating. Temperature normal.

From this time on he gained strength rapidly. August 6 was the last convulsion. On August 9 he walked unassisted, and since then has worked in the kitchen, has felt well, and has a great appetite.

A comparison of the number of convulsions at the onset and at the last of the disease will show this difference: July 13, spasms every one and a half minutes, or 960 in twenty-four hours. July 31, spasms every forty minutes, or thirty-six in twenty-four hours.

Deducting the time he was asleep leaves on July 31 only fifteen to twenty convulsions in the course of a day.

Owing to the severity of this particular case, and the rarity of tetanus, the writer had invited most of the prominent physicians of the city to call and investigate. They all concur in the opinion that the patient could not possibly have recovered without the use of the antitetanic serum.

During his treatment he was given 1800 cubic centimeters of antitetanic serum hypodermically; chloral hydrate and soda bromide during the spasmodic or convulsive part; and a tonic of arsenic, iron and mercury during convalescence.

Only at one time did he lose consciousness, and that was after a severe convulsion on the second day in hospital. His appetite was ravenous, but it did not become necessary to feed per rectum. His bowels were tight until after the sphincter was relaxed at the time the enema was given. Glycerin and castor oil were used to soften the impacted fecal matter. Morphine sulphate was frequently injected for its anodyne effect.

*A CASE OF ACUTE TRAUMATIC TETANUS CURED BY ANTITETANIC SERUM.*

By J. W. FOSTER, M.D.,  
Kansas City, Mo.

On June 28, 1897, I was called to see Clotelia G., colored, fifteen years old. The patient one week previously had run a nail into the sole of the left foot. There was slight contraction of the masseter and temporal muscles, but no pain, no fever, and the pulse was normal. A cathartic was given and further developments were awaited.

June 29, 8 P.M. Conditions about the same.

June 30, 8 A.M. Pulse 100, temperature 100° F.; slight rigidity of cervical muscles. Ten grains chloral every two hours. Calomel to move bowels.

July 1, 8 A.M. Patient was restless; pulse 110, temperature 99½°.

July 2, 8 A.M. Dorsal and abdominal muscles showed signs of rigidity. Given a

combination of chloral, potassium bromide, extract indian cannabis, and extract hyoscyamus every two hours; patient refused third dose. Pulse 100; temperature normal.

July 3, 8 A.M. Slight pains in the limbs, with more rigidity; facial muscles contracted; no fever; bowels moved. At 4 P.M. gave ten cubic centimeters Parke, Davis & Co.'s antitetanic serum; no rise in temperature. At 8 P.M. ten cubic centimeters antitetanic serum.

July 4, 8 A.M. Rested better through the night; ten cubic centimeters serum. Slept two hours. Took first nourishment—milk, cream, and whiskey. At 2 P.M., more restlessness; no fever; pulse 100. At 8 P.M. conditions were about the same.

July 5, 8 A.M. Pulse 110, temperature 99½°; considerable pain throughout whole body. One-sixth grain morphine hypodermically; after that slept some. Took more nourishment—cream, milk, beef broth. At 4 P.M. pulse was 110, temperature 99½°; ten cubic centimeters serum; quite rigid, but spasms not so pronounced. More serum at 9 P.M. Pulse 114, temperature 100°; one-sixth grain morphine.

July 6. Rested fairly well during night. At 7 P.M., pulse 116, temperature 101°. Bowels moved freely during the day. Ordered tepid baths every two hours to control fever. Spasms more marked on left side, chiefly in hip and leg; muscles of deglutition somewhat involved; quite difficult to swallow without strangling. Spasms lasted from one to one and a half minutes, with interval of three to four minutes. Any undue noise provoked a paroxysm.

July 7, 8 A.M. Passed a fair night; pulse 130, temperature 101°; ten cubic centimeters serum. Paroxysm lighter; intervals of five minutes. Ten cubic centimeters serum at 12 and at 7 P.M. Rather restless during the day; pulse 120, temperature 101½°; one-sixth grain morphine.

July 8, 8 A.M. Rested fairly well during the night; pulse 120, temperature 100°. Still continued sponge-baths every two to three hours. Paroxysms less frequent; duration thirty seconds; intervals of half an hour.

July 9, 7 A.M. Rested badly during night; pulse 110, temperature 100°. Rested better during day. Bowels moved kindly. Took milk, cream, chicken broth. Kept up sponge-baths.

July 10, 7 A.M. Rested fairly well during night; pulse 110, temperature 99°. No medicine, but half a drachm of the bromide mix-

ture mentioned above every four to six hours. Rested quite well during day. Took nourishment freely. At 7 P.M. pulse was 120, temperature 99°.

July 11, 8 A.M. Rather restless during night; appetite fair; beef broth with cream. Pulse 110, temperature 98°.

July 12, 8 A.M. Slept well Sunday night. Muscles of arms and chest somewhat relaxed, but quite a good deal of rigidity of whole body; bowels moved kindly.

From this on the patient made a rapid recovery. This being the fourteenth day I only visited the case every three or four days. At the end of the third week standing and walking were possible; at the end of the fourth week the patient came down to my office perfectly well.

To summarize: The disease reached its climax about the tenth day, then gradually subsided. Highest pulse-rate 130; highest temperature 102°. Very little medicine was given. On the 3d of July Dr. John Punton and Dr. G. O. Coffin were called in consultation, and it was decided to begin the use of Parke, Davis & Co.'s antitetanic serum; only three bottles were used during the treatment of the case.

There was great difficulty of breathing part of the time, due to violent tonic contraction of the chest muscles. The kidneys throughout showed no particular involvement; in fact, all the viscera seemed to act in harmony.

*CASE OF ACUTE EMPYEMA OCCURRING  
WITH TROUPOUS PNEUMONIA;  
THORACOCENTESIS;  
RECOVERY.*

---

J. COLES BRICK, M.D.,

Assistant Demonstrator Anatomy, Jefferson Medical College;  
Clinical Assistant Surgical Out-patient Department,  
Jefferson Medical College Hospital.

---

The following case occurred during the writer's term of service as interne at the Philadelphia Hospital, and is reported with the permission of the visiting physician, Dr. Salinger:

- The patient, a colored man aged twenty-two, was admitted to the hospital with a history of having slept in wet clothing the previous night, and of having had a chill lasting for a half-hour. The physical examination showed the patient to be well nourished, but with a slight infraclavicular depression of the right side. Heart displaced to the right four centimeters. Crepitant râles

were heard over the lower lobe of the left lung; blood-streaked expectoration. Dulness extended over the left lung as high as the sixth rib anteriorly, and to about the same level posteriorly when the patient was in the sitting posture—change of position causing change of the area of dulness. Obliteration of the semilunar space of Traube. Diagnosis was made of croupous pneumonia, and pleurisy with effusion.

The pneumonic process proceeded, and on the third day the dyspnea became marked, although there was no change in the cardiac position. Aspiration was decided on, and was done as follows: The midaxillary area down to the costal margin was prepared aseptically, by washing with soap and water, then with alcohol, and finally with bichloride 1:1000. A Potain aspirator was used. A sharp trocar and cannula were selected and boiled. The operator's hands having been carefully aseptitized, and the patient placed in a semi-recumbent position, the trocar was inserted between the sixth and seventh ribs in the axillary line. The stop which controlled the tube leading into the exhaust reservoir was opened, but no fluid passed—in other words, a "dry tap." The wound was dressed with aseptic cotton covered with collodion.

The aspirator was then tested; the cannula was free, but in the angle of the tube some distance away a clot of dry blood from previous use was found.

On the following day, the respirations having risen to 44 per minute, and the patient suffering great discomfort, aspiration was repeated very near the first puncture, and about two ounces of pus withdrawn. There was a rise of one degree in the temperature following the operation, but the respirations fell to 28, with much relief to the patient. The apex beat was seen to have moved .5 centimeter nearer normal. Microscopical examination of the fluid was made at once, and large numbers of pus cells and staphylococci were found. Cultivation and inoculation experiments were not carried out. The condition of the patient gradually improved, and on the following day the apex had moved .5 centimeter more to the left, and on the next day, or the sixth of the illness, the temperature had fallen four degrees and the respirations were 18 per minute, the apex being now three centimeters from the normal position.

A large area of dulness remaining, and the heart being still displaced, aspiration was

done a third time, the puncture being between the seventh and eighth ribs. No pus was found, but a small quantity of blood flowed into the aspirator bottle, being undoubtedly from the lung substance. From this time the case made good progress, the lung cleared up, and with the exception of a few fine râles at the right apex, beneath the depressed area noted, the breath sounds were normal. The sputum was examined at this time for tubercle bacilli, and a few found. The treatment now consisted of increasing doses of strychnine pushed to tolerance, with nourishing food; and the heart gradually resumed its proper place. At the expiration of six weeks examination of the sputum failed to show the presence of Koch's bacillus, the heart was normally placed, and the patient was discharged.

Several questions suggest themselves in studying the above case, but before proceeding to their discussion a brief history of pyothorax and aspiration might not prove uninteresting.

The treatment of pyothorax dates back to the remotest antiquity. Pliny in his "History of Nature," book vii, describes the case of Phareus, who after having been given up by his physicians sought death on the battlefield, but receiving a spear-thrust in the chest, pus escaped from the wound, and he recovered. Hippocrates in his "De Morbis Popularibus" describes not only the diagnosis but the treatment of pyothorax. He calls especial attention to washing the patients very frequently with very warm water before the operation was performed; and as Beck in his interesting article on Pyothorax\* says, "Does not this extraordinary cleanliness appear like the dawn of aseptic principles?" Celsus and Galen repeated the doctrines of Hippocrates, Galen probably being the inventor of the aspirating syringe; but later on the whole subject dropped into oblivion. Drouin in the fifteenth century was the first to use the trocar and cannula, but the mortality rose to such a height that aspiration fell into disrepute. Ambrose Paré, Guy de Chauliac, and Fabricius ab Aquapendente tried to restore the old Hippocratic operation of incision to favor, but with only slight success. Corvisart, the surgeon of Napoleon, said thoracotomy always accelerated death. Dupuytren when suffering from pyothorax declined to be operated on. Velpeau had lost all his cases of pyothorax,

and Dupuytren had only seen four recoveries. Bowditch in 1852 advocated and used aspiration largely for diagnostic purposes, but it was only when Lister showed why it was unsafe that aspiration and incision for pleural effusions were restored to favor.

*In the case we have reported, what caused the heart displacement?* First, there are the pleuritic effusions, and beside empyema there are the ordinary effusions of pleurisy—passive effusions (hydrothorax), in the last stages of cardiac or renal disease; effusions mixed with air or blood, of malignant disease, or advanced tuberculosis; hemorrhagic pleurisies; chylothorax, from injury to thoracic duct; pleurisy by traumatic infection. Other causes are valvular incompetence with hypertrophy, tumors of various kinds, plastic pericarditis, and the perforation of a subphrenic abscess into the pleural sac. From the age and previous history of the patient, and the result of the aspiration, with the subsequent disappearance of the cardiac displacement, a reasonable answer to the question would be undoubtedly pleuritic effusion, which had become an empyema.

*Was the case not an old tubercular pleurisy with an acute empyema added?* As a large number of inflammations of the pleura, exclusive of trauma, have their origin in tubercular processes, this view is plausible, but the very slight lung involvement, and the apparently complete absorption of the exudate, are against this view and in favor of a metapneumonic pleurisy, afterward becoming an empyema. For "when the pleuritis is due to this (Koch's bacillus) as the irritating agent, the effusion is found to be sterile;"\* yet to quote further, "it undoubtedly furnishes a favorable culture medium for other organisms, notably the pneumococcus and staphylococcus." It is possible that the tubercular lesion of the lung had set up a slight pleuritis, a sterile exudate had been poured forth, which had become infected by the pneumococcus, and later by the staphylococcus, as the latter germ only was found in the specimen. In 109 cases of pyothorax examined by Netter, he found the streptococcus fifty-one times, pneumococcus thirty-two times, tubercle bacillus twelve times. Beck's report† shows of forty-nine cases, streptococci were present sixteen times, pneumococci ten times, and tubercle bacilli three times; and as he further says: "In tubercular pyothorax

\* *International Medical Magazine*, January, 1897.

\*Fowler, *Annals of Surgery*, November, 1896.

† *International Medical Magazine*, January, 1897.

the tubercle bacillus is in the majority of cases absent; its absence therefore does not disprove the presence of tuberculosis." The only objections to the view that this was a case of slight tubercular pleurisy becoming an acute empyema are the absence of a thickened pleura, and the early and complete absorption of the exudate. Would not the result in this case be an argument for the therapeutic value of early aspiration?

*Did the aspiration convert a simple pleuritic effusion into an empyema by infective process?* This is possible but not probable, for the trocar and cannula were boiled and the greatest care taken to prevent such an accident. The fact that a clot was found in the tube of the aspirator we do not think proves that infection took place, as it remained a dry inert mass at some distance from the wound—simply preventing the exhaust from acting on the pleural contents. Then, again, no fluid was withdrawn; the history of most cases of infection has been that a simple serous effusion was converted into a purulent effusion. It is impossible to know when the effusion became purulent, for the heart displacement did not increase when the dyspnea became marked, remaining the same as when the patient was first seen; and yet the effusion was undoubtedly the cause of the dyspnea, for the latter immediately improved when aspiration was done.

*For so much heart displacement why was there not more than two ounces of fluid found?* It is by no means certain that all the pus was withdrawn, in fact it is more than probable that a quantity remained; therefore the ratio between the cardiac displacement and the amount of fluid withdrawn is not a true one. As Fowler says, "in even small effusions, the presence of the effused fluid so increases the dyspnea as to become a source of great discomfort, or threaten life."

A mass of coagulum, a fibrous pleural band, an adhesion, or a small pocket of pus, might have been opened, which would account for the small amount evacuated.

*Would the empyema have been absorbed without aspiration?* According to Kracht, quoted by Paget,\* "no micro-organisms are present in simple serous effusion; but in empyema following pneumonia the pneumococci of Fränkel are the inciting cause, for in the early stage these alone are found. The pneumococci may fail to overcome the resistance of the tissues, may die, undergo

degenerative changes, and with the effusion which they have caused be absorbed." In our case the staphylococci were found and not the pneumococci, and whether the effusion was originally a tubercular or meta-pneumococcal effusion can only be determined inferentially.

Belief in the idiopathic variety of pleuritic effusion is not held by many writers of note. The results of investigators in this kind of work—viz., A. Fränkel, E. Levy, Prudden, Koplick, Netter, and Weichselbaum—show the pyogenous bacterium most frequently found in pyothorax to be the streptococcus, and Netter has shown a pneumococcic may cause a staphylococcic empyema.

Pel\* reports three cases, two after pneumonia, the third of doubtful origin; and Bouveret† reports one case—all of which were proven by aspiration to be empyema, and all were absorbed.

In our case therefore it is possible that the absorption would have taken place.

*Did aspiration hasten or retard recovery?* The peculiar effect laparotomy has on a tubercular peritonitis might explain the early recovery of our case. The aspiration did relieve the dyspnea and thereby improved the general condition, and at the same time removed two ounces of septic material; so that on the whole we incline to the view that recovery was accelerated by our procedure.

*When is the proper time to aspirate in pleuritic effusions?* Hippocrates advised the fifteenth day; Bowditch three weeks. Bernier, and later Fox, by a careful comparative study of a large number of cases, found that the mortality was doubled following the introduction of early thoracocentesis. Dr. Washburne's rule in acute pleurisy (cases of pleurisy caused by the pneumococcus, *Med.-Chir. Soc. Trans.*, 1894, p. 179) is, "Let alone for two or three weeks." This is concurred in by Sir Thos. Watson, Fräntzel, de Haviland Hall, Gerhardt, and Clifford Allbutt, who advise withdrawal of fluid, if absorption does not take place in this length of time. "But it is better to be too soon than too late, for it is impossible to tell the amount of internal pressure by external signs, and the relief of this pressure may be of the greatest importance, the policy of delay serving no good purpose."‡

† "Traité de l'Empyème," Paris, 1888.

‡ Stephen Paget.

\* Surgery of the Chest.

In spite of the array of authorities quoted we think the marked dyspnea of our case justified the early aspiration, and the result proved the correctness of our reasoning.

*The choice of methods—incision or aspiration?* The balance of advantages is in favor of aspiration, as incision can always be done if aspiration is unsuccessful (Paget).

*The best point for the introduction of the trocar?* Walther (*Annals of Surgery*, December, 1889, 455) says: "In point of election for incision by anatomical research the eighth interspace posteriorly is recommended in the largest number of cases. Lay the patient on the sound side, seek the ninth rib, and make the incision along its upper edge—three fingers' breadth anterior to the spinous process of the vertebra. The intercostal nerves and arteries in this operation are not injured." Mr. Goodlee's rule is "opposite the ninth rib just outside the angle of the scapula." "The opening in the chest-wall should be made in the midaxillary line at the level of the sixth rib, as this is the part to which the lung last expands."\* To lessen the liability of infection the following is of value: "The skin must be dislodged before introducing the needle, so that the stitch-canal in the skin and the one in the underlying tissues shall not be in line."† Experience has taught us that the axillary line, high enough to clear and prevent the bulging of the diaphragm, is very satisfactory, and also allows the patient to lie on the back or in the semirecumbent position during the operation.

*Dangers of Aspiration.*—The heart, diaphragm, lung, or abdominal organs may be wounded. The great Laennec himself had this accident happen to him. Sudden death and pleuritic epilepsy should be included as among the dangers. Fräntzel showed post mortem a case of hemorrhage into the pleural cavity following a negative exploratory puncture. Paget reports a fatal case from injury to the lung.

*Should the fluid be withdrawn rapidly or slowly?* If the amount is small it may be withdrawn rapidly, but if present in large quantity, all writers on the subject agree that slow withdrawal is safer.

*Is tuberculosis a contraindication for operative interference?* Writers differ. Kluster,‡ who has reported 109 operations for em-

pyema, thirty-one having tuberculosis, cured nine cases, improved nine, and thirteen died. He claims that the great relief afforded justifies the operation. Still a man may live for years with a tubercular empyema, or a latent tuberculosis of the lungs might be lighted up by an operation for empyema. Activity of the circulation in the lung tissue was supposed to be a protection against tubercular affections, but this is questioned now, for "Laennec in the early history of systematic study of tubercular affections of the lungs asserted his belief that stasis was incompatible with the progress of pulmonary tubercular affections; and Bier's observations, supported by those of Mikulicz and Miller in the treatment of tubercular joint-disease, by means of a constricting bandage so placed as to produce venous congestion of the parts, go far towards confirming the views of Laennec in this particular."\*

Whether operation in a selected case is justified must always depend on the personal equation, as no hard and fast rule can be laid down.

If the case be simply pleural effusion, which is not causing discomfort, then *laissez faire*—let well enough alone; also, if there be lung tuberculosis, hesitate before operation. But if the pressure signs are grave then aspirate in effusion, but in an empyema operate with a view of obliteration of the cavity, by a simple resection, a Schede or Delorme flap operation.

#### SUCCESS OF ARGONIN IN GONORRHEA.

Basing his assertions on the effects obtained in thirty-three cases of more or less chronic gonorrhea, none recent, ZYDLOVITSCH (*Gazette Médicale de Liege*, Aug. 5, 1897) recommends argonin as superior to all other medication for this purpose. It causes the rapid disappearance of the gonococci; does not aggravate the pathologic process, but attenuates it. It should be continued until no gonococci are discovered in the course of three to five examinations at three-day intervals. The argonin is injected into the anterior portion of the urethra in a 1½-per-cent. solution five times a day, and retained five minutes. The posterior portion is treated with a 2.5-per-cent. solution instilled; the consecutive catarrh with astringents.—*Journal of the American Medical Association*, Sept. 18, 1897.

### THE VALUE OF ANTIPYRIN IN LABOR.

The very extraordinary number of ailments in which antipyrin has proved itself useful leads one on one hand to believe all that can be said in its favor, and on the other to doubt the possibility of its proving efficacious in any additional conditions to those in which we already employ it. It is worthy of note, however, that very shortly after antipyrin was first brought forward as a pain reliever several clinicians suggested its use for the purpose of relieving the pains of labor. It is not surprising, therefore, to find that it has been largely used, and that we are now in a position to decide as to its pain-relieving powers in the parturient state. Increasing knowledge of this drug has certainly shown that whatever power for good it has is confined to practically one stage of delivery. It seems hardly necessary to emphasize the fact that it can under no circumstances supplant the ordinary anesthetics, and it must be remembered that the coal-tar products prove themselves useful in those forms of pain which may be called nerve-lesions, and are

usually practically powerless in the pains of inflammatory processes. According to the studies of Misrachi it is a useless remedy for the pains of a perfectly normal labor, but finds its chief usefulness in those cases where the pains are so excessive as to reflexly interfere with the proper uterine contractions. In this condition he asserts that it is most efficient. Misrachi decides, too, that it is indicated in tedious labor when the pains are severe. He also believes that it is useful when the liquor amnii has been discharged too early and where there is rigidity of the os. In regard to the second stage of labor Misrachi concludes that antipyrin is useless. There is evidence, however, that antipyrin has considerable ability to relieve the so-called after-pains. It is also seemingly a fact that antipyrin may be used with some success for the purpose of quieting a tendency to the development of pains before the full term has been reached. If it is intended to use antipyrin for the purpose of arresting a threatened miscarriage, then its dose must be very large—as much as thirty or forty grains given in two or three doses of fifteen grains each at half-hour or hour intervals.

### THE USE OF FULL DOSES OF NUX VOMICA IN THE TREATMENT OF INSUFFICIENCY OF THE OCULAR MUSCLES.

Whether the reader of this editorial believes with Stevens of New York and other ophthalmologists that insufficiencies of the ocular muscles are capable of producing grave secondary nervous manifestations, or whether he belongs to that school which casts grave doubt upon these views, matters little. Every ophthalmologist and many general practitioners recognize the fact that insufficiency of the ocular muscles produces much headache and other discomforts, and while it is true that the proper glassing of these patients gives them great relief, either at once or in time, it is also a fact that the physician or ophthalmologist who administers drugs properly can materially aid the patient on his road toward recovery. In this connection it is of interest to note the value of full doses of nux vomica. There can be no doubt, in patients who have used their eyes excessively, at the same time suffering from insufficiencies of the ocular muscles, that rapidly ascending doses of this drug give them very extraordinary relief, particularly if at the same time there is given with it

some arsenic, or if anemia is marked some easily assimilated preparation of iron.

In the THERAPEUTIC GAZETTE for 1886 Dr. Musser, of Philadelphia, published an interesting clinical paper in which his experiments seemed to prove that the dosage of nux vomica was in inverse proportion to the age of the patient, or in other words that the susceptibility increased with the age; and this is of practical importance to ophthalmologists who desire to administer nux vomica for the purpose named, because it shows that children, who frequently suffer from ocular insufficiencies, can be given full doses of nux vomica with safety. One of Musser's patients took 200 drops three times a day, and he also found between the ages of fifteen and forty that forty-five drops three times a day were generally well borne. Because of these studies de Schweinitz began using full doses of tincture of nux vomica for ocular insufficiency with surprising results, as long ago reported in the *Medical News*; and he also found that he got much better results from administering nux vomica in one of its official preparations than he did if he gave strychnine, as this single alkaloid of nux vomica did not seem to possess the therapeutic advantages of the comparatively crude preparation, perhaps because the patient was deprived of the brucine, which may be therapeutically active in failure of the ocular muscles. As pointed out by de Schweinitz, and as thoroughly endorsed by subsequent observation, it is to be remembered that full doses of nux vomica can only be given to such patients if there are no evidences whatever of retinitis or retinal irritability characterized by dread of light and other symptoms. If it is given to such patients the headache and photophobia will become worse, and the patient instead of improving under the nux vomica will complain bitterly of the exaggeration of his symptoms. It is important to remember that while moderate doses, may be given at first for this condition, the best therapeutic results are only to be obtained by the use of this drug in ascending doses, in much the same way that we give increasing amounts of Fowler's solution in chorea.

#### THE TREATMENT OF TETANUS BY ANTITETANIC SERUM.

In this number of the THERAPEUTIC GAZETTE are reported two cases of tetanus successfully treated by antitetanic serum.

Considering the salient features of these

cases, we find that in the one treated by Dr. Foster the period of incubation was seven days; that the spasms beginning in the masseter and temporal muscles in the next four days had become general; that there was a slight fever, and that the pulse was continually hurried and ran as high as 130; that amelioration of the spasms was not noticed until the second day after the administration of the first dose of antitetanic serum, in the meantime forty centimeters of this drug having been administered hypodermically; that on the following day the spasms were even more marked, occurring every one or two minutes and lasting three or four minutes at a time; and that after this, the serum being continued, improvement was progressive, but the pulse remained hurried for several days.

In Dr. Coffin's case the period of incubation was four days. In the next six days the spasms had become universal and recurred every minute and a half. The highest temperature was  $105\frac{1}{2}^{\circ}$ , at the time the patient was received into the hospital, and the highest pulse-rate 128. This case distinctly belonged to the fulminant type. He received 1800 cubic centimeters of antitetanic serum hypodermically, together with sedatives during the convulsive periods. His convalescence in so far as the vital phenomena were concerned was uninterrupted from the time of beginning the serum treatment.

Both of these cases are of peculiar value in establishing the worth of the modern method of treating tetanus. It is but recently that Kanthack, after an exhaustive review of the literature of the entire subject and extensive tabulation of the cases reported up to the period of the publication of his paper, arrived at the conclusion that serum treatment has not actually changed the prognosis in acute and serious cases of tetanus. In milder cases he acknowledges that it may lessen the spasms, the pain, and distress, and may reduce mortality. Indeed it has been claimed that there is not a single well authenticated case of acute traumatic tetanus developed within a week which has been successfully treated by the antitetanic injections. Richter as a result of statistical study states that ninety-five per cent. of all cases with an incubation period of less than ten days die when treated by ordinary methods, and that out of a collection of 717 cases of all kinds eighty per cent. died. Kanthack from his studies found that of the cases treated by Tizzoni's antitoxin 25.8 per cent. died, but this calculation must be received with some

allowance since it concerns only the published cases, and these were not analyzed carefully.

Weir of twenty cases collected, including one observed by himself, reports four deaths, a mortality of twenty per cent. The quantity of serum injected was from thirty to fifty cubic centimeters; the total quantity in any individual case not exceeding 200 cubic centimeters.

Vaillard insists upon the inadequacy of antitoxin in any but the chronic cases of tetanus—*i.e.*, those which spontaneously recover. He and practically all observers, among whom probably Nocard is the most conspicuous, are, however, united in the belief as to the protective value of injections.

It must be admitted that the modern treatment of tetanus is still on trial, but the accumulating evidence is steadily corroborating the inferences gained from bacteriological and laboratory research. These inferences are that man can be protected from tetanus by preventive injection, and by comparatively small doses of the antitoxin; that the toxin of tetanus can be neutralized even after it has been absorbed into the system and has manifested its effects, but that this requires large, often enormous, doses of the antitoxin.

The two cases reported in the present number of the THERAPEUTIC GAZETTE are certainly among the most convincing of any which have yet appeared in medical literature. They both belong to the virulent and almost invariably fatal type of the disease. One, and the more severe of the two, received a very large dose of the antitetanic serum; neither exhibited the slightest toxic symptoms from these injections, unless the rapid pulse could be attributed to them, but this is such a constant accompaniment of tetanus treated by other means that it almost certainly was due to the effect of the toxin and not to the antidote administered. The injections were not followed by suppuration or local pain, and the amelioration of the symptoms was steady and progressive when the system was once brought thoroughly under the influence of the medication. Of course it cannot positively be said that either or both of these cases would have necessarily died under another method of treatment, but the evidence is strongly in this direction, and it will need but a few more records of the kind to firmly establish the value of the treatment. It cannot be expected to save all cases. It will infallibly happen that before the disease is treated at all in a certain percentage the patients have already received into the system a fatal dose

of toxin. We can, however, look forward now with some decided hope to lessening the mortality to probably twenty per cent., and perhaps much lower than this.

The method of preparing the antitoxic serum which was used (Parke, Davis & Co.) was as follows:

The serum is produced in essentially the same manner as is the antidiphtheritic serum. The horse, however, is relatively insusceptible to diphtheria and very susceptible to tetanus. From this it results that the immunization is more difficult, more horses are lost in the attempt, and to produce a high degree of immunity requires a much longer time in the case of the antitetanic serum. The tetanus toxin, which is produced by the tetanus germs growing in bouillon, has added to it an amount of preservative sufficient to prevent decomposition. It is usually allowed to stand for a week and then filtered through a Chamberland filter. The strength of the toxin is then measured on guinea-pigs. Knowing the strength of the toxin, and having the temperature record of the horse from the last injection, it is easy enough to figure out the probable amount of this toxin which the animal will stand at the next injection.

Tetanus antitoxin is, as an experimental remedy at least, much more potent than the diphtheria antitoxin—that is to say, a given amount of the immunized serum will protect a greater weight of guinea-pig against the tenfold fatal dose of toxin than will be the case with the diphtheria antitoxin. The reason for this perhaps lies in the fact that the strength of an antitoxin is in some measure proportioned to the amount of toxin that the horse can be gotten accustomed to. In the case of diphtheria immunization a point is reached after a while when the mere bulk of the liquid to be injected prohibits any advance. It is rare that we can obtain a diphtheria toxin that will kill half-grown guinea-pigs in less than 0.01 cubic centimeter, whereas it is easy to produce a tetanus toxin that will kill in one-seventh to one-tenth of this amount. Having a toxin in such concentration the amount that can be subcutaneously injected into the horse is, of course, very much larger than in the case of the diphtheria poison.

Parke, Davis & Co. have bottled their tetanus antitoxin in one-ounce packages, recommending one-third of this amount to be given at a time in an average case of tetanus, the injections to be repeated until the whole amount is used.

## Reports on Therapeutic Progress

### A VISIT TO BAD NAUHEIM, WITH THE PURPOSE OF INVESTIGATING THE "SCHOTT TREATMENT" FOR CHRONIC HEART DISEASE.

In the *Johns Hopkins Hospital Bulletin* for May, 1897, CAMAC tells us that last November, at Dr. Osler's suggestion, he undertook to introduce into the hospital the Schott treatment of exercises and medicated baths for cases of chronic heart disease. After consulting the bibliography of the subject, several cases were placed under treatment according to the instructions contained therein. At once, however, they were confronted by numerous questions, answers to which it seemed quite impossible to find in any of the references at hand. Although the literature dealt at length with changes in the cardiac outline, the position of the cardiac maximum impulse and the respiration, the theories upon which the beneficial effects were based, etc., no answer to such practical questions as the following were given:

1. Is any massage to be employed during or after the bath?
2. What drugs are to be employed during treatment, and what drugs are contraindicated?
3. Should the baths and exercises be given together, or, if separately, which should precede?
4. Are stimulants to be administered before or after the bath?
5. What should be the diet of the patient?
6. Are cases of hydrothorax or ascites to be tapped?

Finding many of these questions unanswered, it was with considerable interest that the writer received Dr. Osler's suggestion to visit Bad Nauheim, the home of the treatment and of Dr. Schott, its originator.

Nauheim is in the Grand Duchy of Hesse, three-quarters of an hour from Frankfurt-on-the-Main and two hours from Homburg. Nearly in the center of the northeastern half of what geologists have called the Mayence Basin (Mainzerbecken), Frankfurt is located, and at the eastern slope of the Johannisberg, the last spur of the Taunus mountains, is situated Bad Nauheim. As one approaches Nauheim he is struck by the great trestlework structures in the midst of the fields. On examining these more closely they are found to be frame structures about 200 to 300 feet long and about 50 feet high, supporting

switches closely stacked one upon another. The salt waters are raised to the top of these trestles and allowed to filter through the interlacing switches, upon which, by the evaporation of the water, the salt is deposited. These switches are removed every few months or so, the salt broken from the branches, ground and refined, and serves as the commercial salt of the surrounding country. The most beautiful forms result from these deposits, and by the clever devices of the natives the most grotesque figures are produced.

An estimation of the commercial value of these works to-day may be made by the value put upon them in 1806, when they were considered by Napoleon an adequate reward to Marshal Louis Nicolas Davout (erroneously written Davoust) for his services in the French army; and again in 1866, when they fell to Hesse-Darmstadt in exchange for Homburg. Since 1834 the reputation of Nauheim for the efficacy of its springs has been steadily coming to the notice of Europeans. Frankfurt, up to this time forming the center and battlefield of many of the German disputes with France, rendered Nauheim scarcely a fit place for invalids.

It was therefore not until 1834 that we begin to hear of Nauheim as a resort for invalids. It was not until 1860, however, that Dr. Beneke, of Marburg, considered scientifically the value of the medicated bath treatment. From 1859 to 1870 several articles by Beneke upon the waters of Nauheim appeared in the *Berliner Klinische Wochenschrift*. From 1870 to 1890 August and Theodore Schott and J. Groedel were frequent contributors on this subject to the *Berliner Klinische Wochenschrift*, also to the *Deutsche Medicinal-Zeitung*. August Schott died, but his brother Theodore continued the work, and published in 1892 an article in the *Lancet*, which caused little comment.

In 1894 W. Bezley Thorn became an ardent advocate of the bath treatment, and published an article in the *Lancet* and also a small book in which he described quite fully the baths and exercises. With the appearance of this systematic little book up to the present the treatment has been very popular in England. Nauheim, its waters, and the resistance exercises, have been frequent topics in English and German medical journals. In France and America the treatment has as yet received no very thorough trial. It is interesting to note here the increase in the number

of visitors from 1871 to 1895. In 1871 the visitors numbered 5249; in 1891, 9244; 1892, 10,272; 1893, 10,384; 1894, 11,681; 1895, 14,136.

Although the season was over when the writer visited Bad Nauheim, he had an opportunity of seeing the baths through the courtesy of Dr. Hirsch, Dr. Schott's assistant, who showed him over the grounds and described very fully the details of the treatment. It can best be described in Dr. Schott's own words: "The springs of Nauheim may be divided into two classes, those suitable for bathing and those suitable for drinking. Together with other ingredients the bath waters contain from two to three per cent. of sodium chloride, from two to three per 1000 of calcium chloride, various salts of iron; above all, very large amounts of carbonic acid. Coming from the depths of the earth, they have a temperature of 82° to 95° F. Springing from a depth of 180 meters, supercharged with carbonic acid gas by the pressure to which they are subjected, the waters gush far above the surface; for example, Spring No. 12 rises to a height of fifty-six feet and falls again in white seething masses." This is a most striking condition; so richly charged with carbonic acid are these waters that the reservoir into which they fall has the appearance of a great mass of clouds. "Conveyed directly from the main by means of subterranean pipes, these waters charged with their natural gas are allowed to completely cover the body of the bather. Little bubbles of gas are seen to immediately cover the whole surface of the body. The waters of Springs Nos. 7 and 12 escape from a pressure of from  $1\frac{1}{2}$  to  $2\frac{1}{2}$  atmospheres, and afford a surf bath which compares accurately with the strongest surf bath of sea water."

The first question which arose when this matter came to be scientifically investigated was, How do these baths and exercises act? That they were very efficacious in the relief of chronic cardiac disease had been demonstrated for some years back, but their action had never been investigated. There are several explanations given; that given by Dr. Schott is in the following words:

"Physiological research of recent years seems to show that the salts held in solution in water externally applied have no direct action on the system; the light and mobile molecules of the gas, on the other hand, pass rapidly through the skin to the corium with its rich supply of blood. We must look upon the salts held in solution as passing by imbi-

bition through the outermost layer of the epidermis, and so acting on the terminal nerves of the skin as to exert a reflex action on the internal organs. The warm baths act in their own peculiar manner on the organism as a whole; increased tissue change seems to be induced by an increase of the oxygen absorbing power of the cells, and hence follows the sense of the need of rest and sleep as an immediate consequence of the bath, as well as influences speedily brought to bear on the nervous system as a whole. Excessive bathing induces an excitable state of the nervous system, sleeplessness, loss of appetite, and consequent loss of strength. The principal changes which ensue in the system and in the function of the special organs are that the heart beats more slowly and strongly, the pulse becomes full and increases in force, and the blood-pressure may rise to the extent of twenty to thirty millimeters of mercury; the breathing becomes regular and quiet, and the capacity of the lungs increased.

"While the patient is in the bath he becomes flushed and a feeling of comfort and warmth ensues, which may even rise to one of an agreeable intoxicating character. Almost invariably the excretion of urine is increased; exudates in the body cavities, especially from the peritoneum, pericardium, and pleura, are absorbed. This latter action and that on the valves of the heart can only be explained on the theory of reflex action produced by influences acting upon the terminal nerves."

Another explanation is that given by Dr. Bezley Thorn, that there is a dilatation of the muscular arteries and afterwards those of the skin, and thus there is a relief of the heart from backward pressure. In Lauder Brunton's massage experiments he demonstrated that more blood flows through the massaged part and that blood-pressure at first rises and then falls, and that on the conclusion of massage more blood collects in the massaged part. These experiments were confirmed by Dr. Oliver. T. Grainger Stewart concluded that the passive exercises improve the circulation of lymph within the tissues, and bring a larger volume of blood into the muscles. He quotes the conclusion of Ludwig to the effect that the capacity of muscles for blood is equal to the combined capacities of the internal organs and the skin. If therefore this be so and Dr. Lauder Brunton's experiments be correct, the increased amount of blood in the muscles must indicate a relief of the congestion in the internal organs.

In Dr. Schott's explanation there are two actions: (1) A cutaneous excitation induced by the mineral and gaseous constituents; and (2) a more prolonged stimulation of the sensory nerves excited by imbibition into the superficial layer of the corium. The salt producing this excitation is the calcium chloride.

Whatever the explanation of their action may be, two points seem established: (1) that the apex beat alters its position; (2) that the degree of cardiac dullness is diminished. These two facts, especially the first one, were most strikingly obvious in their first cases, and both facts were most forcibly demonstrated to the writer in the cases which he saw abroad. One can scarcely credit the results published until he has seen for himself these marked changes.

To quote Dr. Schott again: "The methods of administering the baths are of the greatest importance. It is advisable to begin with a one-per-cent. salt bath containing  $\frac{1}{100}$  of chloride of calcium, freed from gas and at temperatures varying from 92° to 95° F., the bath lasting from six to eight minutes. The course of treatment should be interrupted by frequent intervals of one day. The temperature of the bath should, if possible, be gradually lowered, while the proportion of solids in solution and the duration of the bath are gradually increased. At a later stage it is permissible to proceed to the baths containing carbonic acid. The temperature may then be rapidly lowered, especially if chloride of calcium be added in order to increase the mineral strength of the bath."

The course consists of six baths, the first and the second being simply with salts—calcium chloride and the sodium chloride; the third, fourth, fifth and sixth contain carbonic acid as well as these salts.

The preparation of the baths artificially was taken up especially by W. Bezley Thorn in London in 1895, since which time Ewart, Bowles and Broadbent have employed them in London, Moeller in Brussels, and Heine-mann in New York. Following the analysis of Nauheim waters made by the chemist Fresenius of Wiesbaden, the artificial baths may be readily prepared. We have now packages made up at the pharmacy, each containing the proportion of salts for the different strengths of the baths, each package corresponding to forty gallons of water, which is just about enough to entirely immerse the body. The baths of different strengths are given to appropriate cases.

The author has not attempted in this note in any way to speak for or against the treatment nor to report cases. He has thought it best for the present simply to give an outline of the trip to Bad Nauheim, the purpose of which was to see the effects of the treatment and to learn something about it with the object of trying it in the hospital at Johns Hopkins. They have now five cases under treatment, and the writer trusts by keeping careful records of the effects of these baths and exercises that he will be able to pass judgment upon the weak as well as the strong points of the method. Only by a careful trial can one place himself in a position either to recommend or to condemn the treatment.

In regard to the exercises, which are worthy of a lengthy description, something must be said. They consist of nineteen movements, each movement restrained by the very lightest resistance. This part of the treatment, under the supervision of a physician, is entrusted to the nurses, to whom careful instructions have been given as to the method of carrying it out.

The following are the instructions laid down for the nurses in the administration of the bath:

1. Always understand clearly from the doctor the following points: (1) Strength of the bath to be given; (2) temperature of the bath; (3) length of time patient is to remain in the bath. *Note.*—Give the bath in the morning unless otherwise ordered.

2. Observe carefully the chart and note the points therein called for. (1) Give bath on an empty stomach; (2) note the time from the moment patient is immersed to that when he is taken out; (3) allow the patient to make as little exertion as possible—assist him in every way; (4) a sheet may be drawn over the tub, but not around the patient; (5) be sure the entire body is immersed; (6) keep the finger on the pulse during the entire time the patient is in the bath.

Cyanosis (bluing of the face), dyspnea (difficult breathing), apnea (gasping), inappreciable pulse: On the appearance of any of these, take the patient out of the bath immediately, put him to bed, and keep him as quiet as possible. Friction while in the bath is not necessary, but if the fingers and toes become bluish the extremities may be rubbed slightly towards the trunk. Friction should be cautiously employed; when the patient is out of the tub rub him to a glow; give him a glass of milk or cup of bouillon and allow him to rest for an hour.

As to diet, small quantity every four hours. Meat—boiled chicken, mutton chops; eggs, two a day; oysters, raw or panned; vegetables—peas, beans, lettuce; liquids—beef-tea, bouillon, cocoa, lemonade, milk. *Note.*—Never give more than four ounces of fluid at a time; should be sipped. Wine—Port, Rhine, sherry, brandy, drachm to half-ounce.

*Note.*—Something light (cocoa and toast) should be taken one-half hour before the bath; something light and hot (bouillon, milk punch, and toasted crackers) should be taken directly after the bath. If the heart's action is poor, sherry, brandy or port wine may be given after the bath. Last meal to be taken three hours before retiring.

Bath No. 1: Sodium chloride, 4 pounds; cal. chlor., 6 ounces.

Bath No. 2: Sodium chloride, 5 pounds; cal. chlor., 8 ounces.

Bath No. 3: Sodium chloride, 6 pounds; cal. chlor., 10 ounces; sodium bicarb., 6 ounces; HCl, 7 ounces.

Bath No. 4: Sodium chloride, 7 pounds; cal. chlor., 10 ounces; sodium bicarb., 8 ounces; HCl, 12 ounces.

Bath No. 5: Sodium chloride, 9 pounds; cal. chlor., 11 ounces; sodium bicarb., 1 pound; HCl, 1 pound.

Bath No. 6: Sodium chloride, 11 pounds; cal. chlor., 12 ounces; sodium bicarb., 1 pound; HCl, 2 pounds.

Each bath consists of forty gallons of water.

*Note.*—By using a little more  $\text{NaHCO}_3$  than is required to take up the HCl, the metal tubs may be employed without doing them any harm.

The exercises are called by Dr. Schott "Widerstandgymnastik," or resistance gymnastics, and consist in slow movements executed by the patient and resisted by the physician or operator. A short interval is allowed after each movement, during which the patient sits down. The exertion employed must be very small, and should cause no increase in respiratory movements, flushing, or pallor. The patient should be loosely and lightly clothed, and instructed to breathe quietly. The resistance made should be of such a kind that the patient may always feel himself easily the master. The operator must not grasp or in any way constrict the limb, but should oppose by the hand held flatly. The movements are nineteen in number.

*Arm.* (1) Arms extended in front of body on a level with shoulder, hands meeting; arms carried out until in line, and brought back to original position. (2) Arms hanging at sides, palms forwards; arms flexed at elbow until tips of fingers touch shoulder; back to original position; one arm only moved at a time. (3) Arms down, palms forward, arms carried outwards and upwards until thumbs meet over head; back to original position; one arm only moved at a time. Not always advisable. (4) Hands in front of abdomen, fingers flexed so that the second phalanges touch those of opposite hand; arms raised until hands rest on top of head; back to original position. (5) Arms down, palms against thighs, arms raised in parallel planes as high as possible; back to original position.

*Trunk.* (6) Trunk flexed on hips; return to original position. Resist with both hands. (7) Trunk rotated to left, to right; return to original position. Resist with both hands. (8) Trunk flexed laterally. Resist with both hands. (9) As No. 1, but fists clenched. Resist with both hands. (10) As No. 2, but fist clenched.

*Large Arm Movements.* (11) Arms down, palms against thighs, each in turn raised forwards and upwards until arm is alongside of ear, then turned outward, and arm descends backwards. Not always safe. (12) Arms down, palms to thighs, both together moved backward in parallel planes as far as possible without bending the trunk forwards. Not always safe.

*Legs.* (13) Thighs in turn flexed on trunk, opposite hand resting on chair. (14) Lower extremities in turn extended fully, and bent on trunk forward and backward to extreme limits of movement, opposite hand resting on chair. (15) Legs in turn flexed on thigh, both hands on chair. (16) Feet together, lower extremities in turn abducted as far as possible and brought back to original position; opposite hand on chair.

*Hands and Feet.* (17) The arms, extended horizontally outward, are rotated from the shoulder-joint to the extreme limits forwards and backwards. (18) The hands in turn are extended and flexed on the forearm to extreme limits, and brought back in line with arm. Resist with both hands. (19) The feet in turn are flexed and extended to extreme limits, and then brought back to their natural position. Resist with both hands.

The writer has arranged these in five groups, as in this way they may be more readily committed to memory.

1. Each movement to be performed slowly and evenly at a uniform rate.

2. No movement to be repeated twice in succession in the same limb or group of muscles.

3. Each single or combined movement to be followed by interval of rest. Count five.

4. Patient's breathing should not be accelerated. Avoid (1) dilatation of the alæ nasi (dilating of nostrils); (2) drawing of corners of mouth; (3) duskiness and pallor of cheeks and lips; (4) yawning; (5) sweating; (6) palpitation.

If any of the above, make a complete interval, or if excessive, stop the exercises for the day.

5. Direct the patient to breathe regularly. If he holds his breath make him count in a whisper.

6. Do not constrict the part which is being moved.

#### SOME RECENT ADDITIONS TO CUTANEOUS THERAPEUTICS.

DUHRING (*American Journal of the Medical Sciences*, April, 1897) recommends in cases of eczema of the forehead, where there is considerable thickening of the skin and exaggeration of the natural folds and lines, with hyperesthesia, the use of camphor as follows:

- ℞ Camphoræ,  $\frac{1}{4}$  drachm;  
Emplast. plumbi, 3 drachms;  
Vaselin, 3 drachms;  
Ol. olivæ, 1 drachm.

M.

The amount of camphor may be lessened should it cause burning sensations. When heat and itching are prominent symptoms in eczema of the face, an ointment of acetanilid, forty to eighty grains in an ounce of cold cream, from its anesthetic and cooling properties, serves to allay these sensations. In several desperate cases of eczema of the anus he has obtained much ease from the distressing burning and itching complained of by the use of:

- ℞ Sulph. ppt., 40 grains;  
Naphthol., 20 grains;  
Morphine hydrochlor., 2 grains;  
Zinci carbonat., 60 grains;  
Ceratum galeni, 480 grains.

M.

Unna (*British Medical Journal*, London, Oct. 17, 1896) suggested, under the name gelanthum, a solution of gelatin and tragacanth as a watery varnish, but the method of preparing it was tedious. Skinner (*British Journal of Dermatology* London, February

and May, 1897) has simplified it. Exactly the same result, he says, can be attained by swelling tragacanth and gelatin with water separately on a steam-bath for twenty-four hours, pressing through muslin while still hot, mixing, adding some glycerin, placing in the bath again for about an hour, straining, then making up to the required bulk with water in which some thymol has been dissolved to preserve the compound.

- ℞ Gum tragacanth,  $2\frac{1}{4}$  drachms;  
Gelatin. opt., 2 drachms;  
Glycerini, 6 drachms;  
Thymol,  $\frac{1}{4}$  grain;  
Aq. dest., q. s.

Place the tragacanth and gelatin each in ten ounces of water in covered jars, and make the final quantity up to twelve ounces with water.

This yields a uniform semiliquid preparation. It may be applied as an ordinary ointment in the first place, afterwards being painted on with a camel's-hair brush, thus giving a protective film, which dries in from two to ten minutes, and is plastic, protective, and emollient. Another useful "film" is obtained when glycerin of starch is smeared thinly on the skin and allowed to dry on. The film produced is comparable to one formed by the purest gelatin, and is not so obtrusive. It is essential that it be allowed to become dry instead of rubbing it off the skin with a towel. An acetone collodion containing a little camphor is a very serviceable one, though not absolutely transparent: thus pyroxyline 10 grains, camphor 3 grains, acetone 1 ounce. Oil of cade or the tars generally mix best with acetone collodion, ichthyol with that made with ether and alcohol. Skinner also notes that calamine as ordinarily met with is very unsatisfactory, not only in its color, but also in its composition. If a good oxide of zinc be exclusively used for lotions or powders, reliance can be placed that the best and that most free from grittiness is provided. If boric acid is prescribed, the pulvis subtilissimus should be specified, and care should be taken that all soap is washed off the skin, as it is soluble, and will decompose any left on, which may cause the irritation sometimes complained of.

Schütz of Frankfort (*Arch. für Dermat. und Syph.*, Wien, 1897, heft 1), finding the severe treatment of lupus erythematosus not only led to irritation and aggravation of the disease, but that cases improved when let alone, and mild, non-irritating ointments applied, has tried weak arsenical solutions locally with success: Liquor arsenicalis, 4.0; aq. dest., 20.0-30.0; chloroformi gutt. 2. This

solution is painted on night and morning and allowed to dry. On the first or second day nothing is observed on the parts painted; on the fourth to sixth, slight swelling, increased redness, and tenderness appear. The further application is discontinued, and the part powdered. In four to eight days the swelling subsides, the part grows pale, and scales. When this has ceased the painting is resumed; in six or eight weeks there is remarkable improvement, and in ten to twelve the lupus is generally cured. No scars remain, except where there has been previous atrophy.—*Edinburgh Medical Journal*, July, 1897.

#### ICHTHYOL IN SMALLPOX.

KOL CASSENKO (*Vratch*, No. 13, 1897) recommends ichthyol as a local application in variola. He has employed it in ten cases (six hospital and four private). Of these eight recovered and two died, the latter being hopeless when admitted. In two of those which recovered the patients were the subjects of advanced chronic disease previous to the attack. The remedy was used as an ointment made as follows: Ichthyol 10, fat 60, lanolin 20; the latter, however, may be, according to the individual case, replaced by chloroform, olive oil, glycerin, etc. The ointment was rubbed in three times a day as soon as the papules became visible. It also proved very beneficial when applied twice a day to the upper part of the trunk in the prodromal stage. As a result there was little or no tenderness at the seats of eruption, the temperature never rose high, and desquamation was almost completed in three or four days from the maturation of the eruption (half the usual duration). In several severe cases where this treatment had been adopted from the very beginning there was no inflammation of the skin and subcutaneous tissue, and the course of the disease was, on the whole, mild in character. No toxic symptoms resulted from the use of the remedy even in children. Rozdestwensky, to whom the author refers in conclusion, has, at the latter's suggestion, tried this mode of treatment in a series of hospital cases and obtained excellent results, which are not yet published.—*British Medical Journal*, June 26, 1897.

#### THE ACTIVE PRINCIPLE OF CASTOR OIL.

Many years ago Buchheim stated that ricinoleic acid is the purgative principle in castor oil, while other observers maintain

that the true active principle is a small quantity of a body derived from the seeds, and held in solution in the oil. The question possesses considerable practical interest, because, if the former view be correct, we cannot hope to diminish the necessary dose, whereas if the latter view be the correct one, and we were able to obtain the active principle in a state of purity, a very small dose of a probably tasteless substance would suffice to produce purgation. In 1890 Meyer strove to show (*Arch. für Exper. Path. und Pharmacol.*, Leipzig, bd. xxviii) that ricinoleic acid and its salts were as active as castor oil, but there is always a suspicion that his preparations contained a small amount of the hypothetical active principle, and that their activity was due to this. He has again returned to the subject (*Arch. für Exper. Path. und Pharmacol.*, Leipzig, 1897, bd. xxxviii), and, after showing that castor oil does not lose its activity by being heated to 300° C., or by treatment with dry hydrochloric acid, by boiling with caustic potash, or by other methods calculated to destroy any known active principle, he comes to the conclusion that ricinoleic acid is the only active substance present in the oil, and that it develops its specific action in the intestine by being saponified and thereby rendered soluble. Ricinoleic acid has, however, no specially irritating properties, and it is difficult to explain its action as a purgative.—*Edinburgh Medical Journal*, July, 1897.

#### ON THE TREATMENT OF DILATED STOMACH.

In *Treatment* of June 24, 1897, WYNTER expresses the view that the treatment of such cases may be divided into the removal of those causes which lead to and maintain dilatation, and the adoption of such means as we possess for promoting the contraction of the organ after dilatation has already occurred.

Among the more common causes of dilatation of the stomach may be mentioned the introduction of excessive quantities of food or drink, of which instances are afforded by vegetable feeders, and those frequent cases which arise among German students from their practise of swallowing many liters of weak beer at their "Kneipen;" the ingestion of food which by its nature or through imperfect mastication is slow of solution, this being still further delayed by feebleness of the digestive juices, by sleep, or by undue activity immediately after meals. The absence of

opposing molars, hurry in taking food, and irregularity in meals, or their following too closely upon one another, are frequent sources of the accumulation of rancid and fermenting residues in the stomach, and ultimate dilatation.

The naturally suggested remedy consists in correcting these defects and in supplying the patient with moderate quantities of easily digested food at proper intervals. In slight cases and those of short standing these measures may be sufficient, but in more severe ones, and especially such as are of long duration, it is necessary in addition to wash out the stomach thoroughly before meals for a day or two and then before bedtime two or three times a week, so as to get rid of fermenting residues and accumulation of partly digested food. The pylorus forms a very effective barrier to solid masses, and tough bodies like thick grape skins and the pulp of an orange have been known to remain for as long as three or even six months in the stomach—the cause of continuous irritation and fermentation. There is no doubt that emetics would be very effectual in many instances, but complete emptying of the stomach by such a process is neither comfortable nor easy to achieve, especially as these patients are rarely young and the stomach is often sluggish as regards muscular contraction.

Provision having been made for emptying and cleansing the stomach from time to time, its contraction may be promoted by the administration of a preprandial pill consisting of strychnine  $\frac{1}{4}$  grain, liquor arsenicalis 4 minims, creosote 1 minim, and extract of gentian 2 grains, twice a day. In extreme cases it is useful to apply the constant current either through the middle of the back or internally by means of a wire protected in a vulcanite tube except for an aperture at the extremity, the second electrode being placed in either case over the epigastrium. A strong current can be borne without inconvenience if gradually increased and diminished, and can be relied upon to allay the pain and vomiting, and to produce contraction of the organ. Another useful measure is massage, really deep and careful pommeling of the epigastric and umbilical regions. This affords a safe and convenient method of rousing contraction and emptying the stomach, regard being had to the position it occupies and the fact that it is commonly dragged down by the weight of its contents, the pylorus remaining looped up and somewhat kinked by the gastro-hepatic omentum.

#### ON THE TREATMENT OF CHRONIC PARENCHYMATOUS NEPHRITIS.

W. P. HERRINGHAM, in the issue of *Treatment* of June 24, 1897, tells us that in chronic parenchymatous nephritis drugs are as nothing compared to management. It used to be thought that for these patients a meat diet was not wholesome. The reasons given were: first, that meat diet increased the albuminuria; and second, that a fish, a farinaceous, or a milk diet was less irritating to, and put less work upon, the kidneys, and produced less of the toxic products which are thought to cause uremia. These ideas are not founded upon fact. Meat diet does not always increase albuminuria, and if it did the loss is so slight that it is quite unimportant. We do not know what toxic products cause uremia, and therefore cannot tell what will produce them. Lastly, there is no evidence whatever that a meat diet is irritating to the kidneys. It would be strange if it were.

The plain fact is that in regulating diet we should almost discard all thought of the kidneys, and consider the general health alone. The same diet will not suit all persons, but for each that should be chosen which will cause the least disturbance of the digestion and the highest state of health. In most cases these ends are best reached by a mixed diet, which should be given with regularity and with frugality. Excess, rich food, irregular meals, are all to be avoided, because they upset digestion. Where appetite is bad a little alcohol is necessary, and for these cases dilute spirits are always wholesomer than wine; a little alcohol does no harm, but the residual substances in wine are very unreliable. Habits of life must also be regulated, and, like diet, much upon the lines of childhood, for adults differ from children chiefly in their power of resistance, and Bright's disease by lessening this puts them back into the infant class. Such patients cannot afford the luxury of carelessness, and must wear flannel, avoid wet and cold, keep early hours at both ends of the day, and take regular exercise. Laziness is as bad as overexertion, for it lessens the internal processes, entirely unknown to us, which produce the interchange of nourishment and waste. It is generally united with greed, which doubles its ill effects. Mental overwork and a sedentary life are again a bad combination, for the first injures the primary and the last the secondary digestion.

To these general rules one condition forms an exception. If we are in fear that the tension in the vascular system will produce ill

effects diet must be kept as low as is safe. To diminish vascular tension nothing equals rest in bed and fluid diet, and short of this, where it can be borne, a vegetarian diet will have the same effect. Most of these patients cannot digest well enough to use it.

This problem, how to feed a patient who has bad digestion and high arterial tension, so that he may have enough to keep him from losing ground, and yet so little that blood-pressure will fall, is one of the most difficult in medicine. Treatment then becomes a system of ingenious catering. The best drug for this condition is iodide of potassium or sodium.

The common ailments of Bright's disease are anemia and indigestion. Patients usually take iron without difficulty, and it is the most important drug in the whole treatment of the complaint. Digestion has to be treated as if Bright's disease were not present.

The symptoms which warn us of danger are anasarca and those called uremic. In chronic parenchymatous nephritis anasarca generally coincides with scanty excretion of urine, and probably depends upon feebleness of the circulation. This itself may, of course, be due to some impurity in the blood acting upon the heart, or the nervous mechanism that controls it. One would expect that cardiac tonics would be the best treatment, but Herringham has not, as a rule, found them to answer. Once or twice striking results have followed the use of digitalis, of diuretin, or of broom tea, but he has seen similar improvement without any drug, and certainly in the majority of cases these drugs have not succeeded. Iodide of potassium in rather large doses, cantharides and belladonna have been recommended by different physicians.

Purging and sweating are said by some to be of more value. For the first the acid tartrate of potash and jalap, or some other resin, is a standard prescription, and Roberts uses it in a large dose every second or third morning in preference to smaller doses more often repeated, because the nausea and unpleasantness has thus to be less often undergone. To increase sweating, hot baths, vapor baths, and pilocarpine can all be used. When patients are very dropsical they cannot be put in a bath, but regular baths are a very good means of prevention. If needs must, the pressure on the skin may be relieved by inserting Southey's tubes, or by acupuncture. The first is the best, because the fluid then runs away and does not irritate the skin. Antiseptic solutions ought to be applied to

the skin before the tubes are inserted and after they are withdrawn, and the tubes themselves should be boiled before they are used. When dropsy comes on without signs of fresh inflammation of the kidney it is a bad augury.

Uremic symptoms are repeated vomiting, paroxysms of dyspnea, persistent headache, drowsiness, coma, and convulsions. We suppose them due to a poisoning of the nervous centers by some impurity in the blood, but we do not know what it is. Vomiting he has seen relieved by hydrocyanic acid; when it is not severe gentian and bicarbonate of sodium suffice. The headache is sometimes cured by cannabis indica, sometimes by phenacetine. One ought also to increase the secretion of urine, if that be possible, by some of the drugs mentioned above. He does not know any drug that will prevent the curious asthmatic attacks that sometimes occur. When they come on an injection of ether is the best treatment. Coma and convulsions are not necessarily fatal, but they are very grave. Purging and sweating are the two main lines of treatment, and chloroform can be given in the convulsions. Much controversy has raged round bleeding in these states. It seems allowed on all sides that it is of no use for coma. The writer has never used it for convulsions, but it used to be much recommended, and speaking *a priori* it seems reasonable. The fact, however, remains that it has gone out of fashion, and perhaps that is better evidence than any written opinion.

#### SERUM TREATMENT OF SYPHILIS.

GROSZ (*Wiener Medizinische Blätter*, 1897, No. 8) gives a critical and historical account of the curative treatment of syphilis by means of serums. He states that three distinct lines have been followed by clinical observers, all of which are asserted to have resulted in some measure of success. These are: (1) Subcutaneous injection of the blood-serum of different animals, these having a natural immunity to the syphilitic infection; (2) animals have been inoculated with blood from patients with secondary syphilis, or have had chancres engrafted under the skin, and then after some time they have been bled and their serum injected into syphilitic patients; (3) the injection into recently infected persons of blood-serum taken from patients with secondary or tertiary syphilis.

1. Feulard used dog's serum, but came to

the conclusion that it had no specific effect. Tommasoli used lamb's serum, in doses of two to eight cubic centimeters, in ten cases of secondary syphilis, and is of opinion that it was more successful than the ordinary methods of treatment. Three of the cases had relapses. Kollman used serum from the sheep, calf, dog, and rabbit, in doses of six cubic centimeters, going up to 165 cubic centimeters altogether; out of twenty-one cases he could not reckon on a single success. There was slight improvement in the general nutrition. Cotterell, giving dog's serum subcutaneously, thought that the course of the disease was favorably affected thereby; while Müller-Kannberg, using horse serum in daily doses of five cubic centimeters in twelve cases, obtained absolutely negative results.

2. Richet, Hericourt, and Triboulet injected dogs with blood from patients who had secondary syphilis, and a few days later bled them and used the serum on men. A patient with gummatous eruptions and ulcers got twelve cubic centimeters of the serum in six days, and in a month the ulcers had healed, while the general condition was greatly improved. The cure was not permanent. Two other cases of tertiary syphilis did much better under similar treatment. Gilbert and Fournier used goats and dogs which had been infected with syphilitic blood (from secondary syphilis), or with excised chancres placed under the skin. Seventeen cases in all were treated with serum obtained from these animals, and the results were as follows: Five were favorable, three were negative, two doubtful; the remaining seven had been treated with mercury in addition, and hence no proper conclusion can be drawn regarding them. Tarnowsky used foals, to which he had administered for a long time different syphilitic material. After using their serum on six patients, he concludes that it has absolutely no ameliorating or curative effect.

3. Bonaduce bled three markedly syphilitic children, and mixed the serum with three times its own amount of water, heated the mixture for ten minutes to 100° C., and then filtered it. A patient with a hard chancre and swollen inguinal glands got every second day ten cubic centimeters, until 120 cubic centimeters had been injected. During this time the local sore and the adenitis disappeared, and seven months after there had been no further sign of syphilis. By heating, Bonaduce thinks he destroyed the syphilitic poison, but not the immunizing body. Pelizzari bled

persons after the secondary stage was over, defibrinated the blood, and injected one or two cubic centimeters until twenty to fifty-five cubic centimeters had been given. In all the patients so treated the secondary symptoms were extremely slight. Boeck, using "tertiary serum" and also hydrocele fluid from a tertiary case, treated seven patients recently infected. In these the secondary symptoms showed themselves but were extremely light, while the primary sore disappeared more rapidly than usual. Wewiorowsky, using a similar serum, concludes also that it affected favorably the course of the disease, but relapses are apt to occur, and it is difficult to determine if the syphilis has been really cured. Spiegler holds that serum from animals cannot be of value, as, so far as we know, immunity cannot be conferred on another species by means of serum from naturally immune species. The same objection holds good, he thinks, to the value of serum from animals which have received injections of syphilitic material. If apparently favorable results are obtained by either of these methods, they are not in any way specific, and are comparable to the local reactions which, for example, tubercular tissues show after the injection of numerous substances. He thinks the same objections do not apply to "tertiary serum."

Grosz concludes that the numerous failures and contradictions simply show that none of the measures hitherto used are of any special value, and that more carefully considered attempts to solve the question are urgently needed.—*Edinburgh Medical Journal*, July, 1897.

#### THE DANGER OF THE VAGINAL INJECTION.

The *New York Medical Journal* of July 3, 1897, deals editorially with this important matter. It states that the case reported by Dr. Wells at a recent meeting of the Society of Alumni of the Charity Hospital—for by its old name they still prefer to call the hospital—may well serve as the text for renewed cautionary remarks as to the danger of the self-administered vaginal injection. In this case a woman who had had a natural labor seventeen days before, and was at the time in a perfectly normal condition, save for a vaginal discharge observed by herself and a state of retroversion of the uterus discovered shortly afterward by Dr. Wells, took it into her head to administer to herself a vaginal

douche. Accordingly she filled a Davidson syringe with plain water, thrust the long rectal nozzle of the instrument into her vagina to the whole length, and squeezed the bulb forcibly. She was at once seized with severe abdominal pain and came very near going into a state of collapse. Having escaped the immediate danger, she suffered from a continuance of the pain, which extended up to the region of the diaphragm and was accompanied with tympanitic distention of the abdomen and a condition highly indicative of general peritonitis. Fortunately, the trouble was soon narrowed down to an inflammatory process seated in the pelvis and giving rise to a massive exudate—a state of things bad enough, to be sure, and tolerably certain to trouble her more or less for years to come, perhaps seriously, but not putting her life in immediate jeopardy. For a time Dr. Wells may well have been in doubt, as he says he was, as to whether he ought not to resort to abdominal section.

It seems quite probable, as Dr. Wells intimates, in view of the retroverted state of the uterus in this case, that the nozzle of the syringe was thrust into the uterine canal, possibly nearly to the fundus of the organ, and septic or at least irritating material forced through a Fallopian tube into the peritoneal cavity. It is stated in the account that the woman had had gonorrhea some years before. The entrance of the nozzle into the uterus, perhaps carrying with it some infectious matter from the vagina, and certainly involving a flooding of the uterine cavity with water that in all probability was not free from septic material, furnishes an obvious and plausible explanation of the manner in which the pelvic inflammation was set up in the case under consideration; but such an occurrence does not by any means constitute the sole mishap of a vaginal injection improperly administered. In order that the injection may be forced into the uterus and through a Fallopian tube, it is not in the least necessary that the nozzle should enter the uterine canal, that one of its apertures should be so situated as to send a stream into the uterus, or that the organ should be retroverted; the one indispensable condition of safety is the provision of a free passage for the outflow of the fluid injected.

If a vaginal douche is to be employed during the puerperal period, says Dr. Wells, it should be given only by the physician or a thoroughly competent nurse. That is perfectly true; but, apart from the puerperal

condition, danger always lurks in a vaginal injection administered without due precaution. How does the uninstructed woman usually proceed when she sets about giving herself a vaginal injection? She squats on some convenient utensil, thrusts in the nozzle, which is almost always of a kind utterly unfit for the purpose, and pumps rapidly (if the syringe is of the bulb type), so as to be over with the unpleasant affair as soon as may be; or hangs the bag high, if she is using an apparatus of the fountain type. In either case, if she has the good luck not to drive the nozzle into her uterus—and there is many a woman going about in tolerable health, so far as she knows, whose uterine orifice will readily admit an ordinary syringe nozzle—in either case, we repeat, she rather suddenly fills her vagina to repletion, even to distention, perhaps with a liquid that, whether by reason of its temperature or of something it holds in solution, may act as a stimulus to spasmodic contraction of the pelvic and perineal muscles. Fortunate is it for her if her vulvo-vaginal sphincter, although never designed to grasp so tiny an object, does not grip the nozzle so vigorously as to imprison the water under a pressure that is very apt to force it into the uterus. It is necessary very often to intrust women with the self-administration of vaginal injections—not, of course, in the lying-in period—and they should always be instructed how to guard against their dangers; and in particular they should be provided with a nozzle so constructed that no amount of contraction about its shank can close the vaginal outlet. Unfortunately, not one nozzle in a thousand is so constructed.—*New York Medical Journal*, July 3, 1897.

#### RECENT STUDIES IN IMMUNITY.

Under this interesting heading the *British Medical Journal* discusses this important subject editorially in its issue of June 26, 1897.

The manner in which the living organism protects itself against the ravages of noxious microbes and their poisonous products is a branch of pathology yielding to no other in interest. Over it the old warfare of the cellular and humoral schools has again been waged, and although we must admit that the brilliant researches of Metchnikoff have established the doctrine of phagocytosis upon a firm basis, it cannot be denied that it fails to explain a certain number of facts which

are better accounted for by the humoral theory, of which Pfeiffer is one of the most ardent and distinguished supporters. Upon the solution of this question hangs one of even greater practical importance, the means by which the more or less permanent immunity following an attack of a specific infective nature is established. The study of so-called antitoxic serums shows that they fall in two groups: those which are truly antitoxic—that is, neutralize microbic poisons—and those which are bactericidal in their action. Most serums possess both these properties to some extent, but one is usually far in excess of the other; thus the serums of cholera and typhoid are mainly bactericidal, those of diphtheria and tetanus mainly antitoxic. A most important contribution to our knowledge of this subject was not long ago made by Wassermann, who succeeded in obtaining from cultivations of the bacillus pyocyaneus a serum possessing both these functions to a marked degree, and also serum possessing one or the other property at will. He found that an animal treated with toxins was protected against both toxins and bacteria, while one treated with bacteria was immune as regards bacteria only. He showed that minimal immunity could be produced by the injection of a single dose of toxin, insufficient to cause severe symptoms; it often appeared on the second day, never later than the fifth. The amount of the immunity varied mathematically with the quantity of toxin injected, but much more with the individual animal. Wassermann made use of the fact that the toxicity of pyocyaneotoxin is but slightly diminished by boiling to attack the vexed problem as to the identity or non-identity of toxic and immunizing substances in bacterial cultures. He found that weakening the toxicity of the toxin diminished *pari passu* its immunizing power, and that consequently—contrary to his formerly expressed opinion—the poison was at the same time the agent conferring immunity.

Turning to the question of ordinary passive immunity—that is, the protection of an animal against an infective disease by means other than its contraction—the author immunized a goat in various ways, and showed that the properties of its serum varied with the method adopted. Thus when the animal was immunized with increasing doses of toxin, its serum was found to possess both antitoxic and bactericidal properties up to a certain limit, beyond which they could not be developed. On further immunization with

increasing doses of sterile living cultures, the bactericidal power of the serum increased, while the antitoxic rapidly diminished. There can hence be no doubt that, although they are not distinguishable by their behavior with chemical or physical reagents, antitoxic and bactericidal substances are different in nature. Thus, while as soon as the former are present in the serum as the result of inoculation with sterile broth cultures, it has also acquired bactericidal properties, it may be powerfully bactericidal without possessing any antitoxic power. To obtain protection against both microbes and toxins, it is therefore necessary to immunize with increasing doses of the latter.

A further interesting research had for its object the elucidation of the true cause of the bactericidal action of antitoxic serum. If this action were an inherent property of the serum it would be possible, by giving a sufficiently large dose of the serum, to kill any number of bacilli introduced into the body of an animal. But this is not the case; although 0.01 cubic centimeter of serum destroyed one loopful of a living culture in the animal body, one cubic centimeter, or 100 times as much, could not destroy three loopfuls. We are, therefore, forced to believe—and this is the case with other micro-organisms besides bacillus pyocyaneus—that an actual reaction of the cells of the body takes place, gradually building up the bactericidal substance out of the inactive protective serum. Till this reaction occurs the microbes may kill the animal, though an excess of immunizing substance is present in its blood.

Wassermann finally made use of the fact that the virulence of pyocyaneotoxin is but little diminished by a temperature of 100° C. to solve the question as to whether the antitoxic serum really destroys the toxin or simply rapidly immunizes the animal against it. That the latter is the case is shown by the result of boiling a mixture of pyocyaneotoxin and serum which was harmless to animals. The protective properties were by this means destroyed, while the toxic were unaffected; on cooling and adding a fresh supply of serum the mixture became again innocuous, proving that the toxin is not destroyed by the serum.

Furthermore, the doses of toxin and serum cannot be increased indefinitely without harm to the animal, which should be the case if they simply produced a harmless mixture. Wassermann never succeeded in rendering more than six times the ordinary fatal dose of pyocyanous poison harmless in the body,

however great the amount of immunizing serum he gave at the same time. There is no doubt, therefore, that in the case of the antitoxic as of the bactericidal substances in protective serums a reaction of the tissues is essential to their efficacy, and that the failure results from the non-development of this reaction.

ON THE TREATMENT OF PHTHISIS BY ANTISEPTICS, WITH SPECIAL REFERENCE TO EUCALYPTUS OIL.

ARTHUR DOUGLAS writes under this interesting heading in *Treatment* of June 24, 1897. He thinks that in treating phthisis, by whatever method adopted, we must bear in mind that we are contending with two forces in the lung, one depending on and possibly following the other. We have first the presence of the tubercle bacillus with its growth and multiplication, and secondly, we have the inflammatory changes arising from them.

It is bearing on the former condition that the author gives a few suggestions, but of course the "changes" must not be lost sight of.

Antiseptic treatment, having for its object the destruction of the tubercle bacilli, is not the sole treatment in phthisis, though necessarily a most important one. If we can by any means remove the cause of the inflammatory changes Nature herself may effect a cure. We cannot expect a permanent cure if our efforts are applied only to these changes, while no measures are being carried out to arrest their cause.

By an antiseptic treatment we may at least hope to cut short the disease, and thereby prolong the life of our patient. But obviously we cannot ever expect to repair the mischief already done to a lung "which consists in absolute tissue loss, and rebuild a partially destroyed" lung. So it is in the early stages of phthisis, when the destruction mentioned is not so extreme, and where a sufficiency of lung remains to carry on the proper aeration of the blood, that we look for the most encouraging results by the use of antiseptics.

In carrying out the antiseptic treatment of phthisis the drug he prefers to employ is the oil obtained from the leaves of the *Eucalyptus globulus*, for the following reasons: (1) It is three times as powerful an antiseptic as carbolic acid in arresting the development of bacteria. (2) It is volatile at ordinary temperatures. (3) Its vapor ozonizes the oxygen

of the air. (4) Its smell is not unpleasant. (5) It is readily absorbed into the system either (a) by the air breathed; (b) by the stomach; or (c) by the skin. (6) After absorption it exercises no irritant or other deleterious effect on the body. (7) It is excreted in considerable amount by the breath. (8) It is a powerful "febrifuge." (9) It reduces the force and frequency of the heart. (10) It increases elimination of urea. (11) It lessens mucous secretion, improving its quality and promoting its expectoration.

The author has frequently administered it in five- to thirty-minim doses for weeks at a time without the manifestation of any symptoms. It can be conveyed into the system either (1) by the mouth, (2) by inhalation, or (3) by inunction. Internally it is conveniently included in the following formula:

R Ol. eucalypti, 5 minims;  
Sp. chloroformi, 10 minims;  
Sp. ætheris, 10 minims;  
Mucilage acacia, 1 drachm;  
Glycerini, ¼ drachm;  
Aq., ad 1 ounce.

M. Sig.: Give this three times a day.

The dose of the oil is gradually increased to ten minims thrice daily.

For "inhalation" he prefers not to use any steam vaporizer, atomizer, or respirator. The object he has in view is to induce the patient to breathe a "saturated atmosphere" without any effort or inconvenience on his part, and without interfering in many cases with his daily avocation.

To do this effectually we proceed to saturate the atmosphere in the patient's bedroom by vapor volatilized from the eucalyptus oil. It is necessary that a large extent of surface should be exposed. This is effected by saturating a long piece of cotton or linen fabric with the oil and stretching it out in several layers, one above another, over a double series of horizontal rails placed parallel to each other. By this means a large area is exposed without occupying too much space. The size of the cotton should be about ten feet long by one foot broad, divided into eight layers or folds. The dry cloth is dipped into a basin containing about six or eight ounces of the oil, being gently squeezed to prevent dripping, and hung in the manner indicated at a temperature of 65° F. Over four-fifths will have been found to have evaporated in six hours.

The cloth should be placed in the patient's room one hour before he retires to rest, the windows and door being closed. On enter-

ing the room the patient should be directed to systematically practise full and deep breathing for five or ten minutes in a standing position. An attendant then rubs into the chest three or four drachms of an ointment of lanolin and eucalyptus oil three drachms to the ounce. This should be completely absorbed.

It is desirable, too, that the patient go through a gentle exercise for ten minutes with light dumb-bells or Indian clubs to promote expansion of chest and muscles. This exercise must always be suspended short of fatigue; there must be no shortness of breath and no dilatation of *alæ nasi*. The patient then retires to bed, the windows and door remaining closed. This treatment should be persistently carried out for weeks and months, and should not be in any way relaxed on improvement taking place. Obviously the cases most benefited are those taken at an early stage; but even in advanced cases no little improvement may be looked for, especially in the amount and freedom of the expectoration, diminished waste, and fever.

It must be understood that while advocating so strongly the antiseptic treatment, other measures are not by any means to be forgotten, as the dietetic, hygienic, and climatic, combined when necessary with tonics, stimulants, and stomachics; on the contrary, they should receive much attention from the physician. At the same time, many cases have shown great improvement by this method alone.

---

*THE TREATMENT OF BRONCHOPNEUMONIA BY RECTAL INJECTIONS OF CREOSOTE.*

In the *Journal des Praticiens* of June 12, 1897, SCHOULL records the results which he has obtained from this method of treatment. He first calls attention to the fact that as long ago as 1892 good results were reported to the Academy of Medicine of Paris as having been obtained by the rectal injection of creosote as an antipyretic in the grave pulmonary complications of typhoid fever, and in 1884 for the treatment of bronchopneumonia. After a further historical summary of these facts Schoull proceeds to express the belief that in bronchopneumonia the favorable action of the creosote depends upon its ability of acting as a bactericide upon the pathogenic micro-organisms which are supposed to be present in this disease. He then

makes the following report as to his statistics: Out of sixty-seven children with bronchopneumonia treated by this method there were sixty-two recoveries and two deaths. In three cases in which the injections were not used there were two deaths and one recovery. In a child of eleven years with croupous pneumonia treated by this means there was also recovery. In adults, out of eleven cases of bronchopneumonia treated by this method there were eleven cases of recovery, and in four croupous pneumonias treated by this method there were three recoveries and one death, a double pneumonia being present in the last condition. These cases were all in men. In women there were fourteen cases of bronchopneumonia with fourteen recoveries, and five cases of croupous pneumonia with five recoveries.

Other statistics have been collected which joined to these give the following results: Out of 130 cases of bronchopneumonia treated by rectal injections of creosote, 125 recovered and only twenty-five died. In ten cases of croupous pneumonia treated with injections, nine recovered and one died. He therefore believes that this method of treatment is an exceedingly favorable one and strongly recommends its employment.

[While these suggestions may be of value in certain cases, we are exceedingly doubtful whether other physicians would have as good results from their employment. It cannot be supposed that the rectal injection of creosote is of any advantage in this condition over its administration by the stomach, except that avoidance of gastric irritation can be obtained, and we do not believe that creosote has any specific influence in this disease.—ED.]

---

*REMARKS ON SYMPHYSEOTOMY.*

In the *Boston Medical and Surgical Journal* of July 8, 1897, ENGELMANN tells us that this operation is one which merits our consideration, more especially as there are those who are inclined to view askance, if not to ignore, the procedure as one of the many fleeting innovations of this progressive era, or as too crude or unsurgical as compared with Cæsarian section, which is now extended, by reason of its success as a hospital operation in elective cases, upon most elastic indications to the minor degrees of pelvic contraction, and even into the realms of version and the forceps, with but little thought of symphyseotomy or premature labor.

This is not a new operation, as it has been known for over a century, and practised even in those early days with fair success and with excellent results as compared with Cæsarian section; yet it has not received the consideration it merits until within the past decade; in that time it has undergone a crucial test, and must now be recognized as one of the accepted procedures of modern obstetric art.

Symphyseotomy holds an unquestioned place in operative midwifery; but its indications are yet to be fixed; its application and limitation to be defined. In the main, we may say that the operation pertains to the intermediate degree of pelvic contraction, that it replaces craniotomy on the living child and premature labor in the earlier months, and must be compared with Cæsarian section on the one hand and high forceps and version on the other, the latter coming in contact with symphyseotomy in the minor contractions, and the former by its relative indications being almost a parallel operation. The indication for pubic section, as he formulates it, is to be found in the slighter disproportion, two centimeters or less, between biparietal and pelvic conjugate, because two centimeters can always be gained by the operation; or, in other words, with the average fetal head of this country, in a pelvis of between seven and nine centimeters ( $2\frac{3}{4}$  to  $3\frac{1}{2}$  inches). As yet the various operators differ somewhat as to the sphere of the operation, at least in so far as its limits are marked by pelvic measurements alone—always an uncertain guide.

Pinard gives the widest scope to symphyseotomy, from a conjugate of eight centimeters ( $3\frac{1}{8}$  inches), above which he resorts to premature labor, to one of five centimeters ( $1\frac{3}{4}$  inches), within the absolute indications of Cæsarian section, thus confining Cæsarian section to a pelvis of less than five centimeters ( $1\frac{3}{4}$  inches).

Leopold allows a much smaller range to the operation, but likewise applies it to the higher degrees of contraction—to those with a conjugate of 7.5 centimeters to 6 centimeters, the limit for absolute Cæsarian section.

Morissani himself does not carry symphyseotomy quite so far, limiting its application to a conjugate between 8.8 centimeters and 6.7 centimeters ( $3\frac{1}{8}$  to  $2\frac{1}{8}$  inches)—very much the class of cases formerly consigned to craniotomy on the living child—and, if elective, to premature labor in the earlier months.

Tarnier gives preference to symphyse-

otomy in pelves of less than eight centimeters, though he reports a series of cases of induced labor in contractions to 6.6 centimeters ( $2\frac{1}{4}$  inches) unfavorable by reason of the high fetal mortality. Leopold limits premature labor to a conjugate between eight centimeters and seven centimeters, cases in which at term he advocates forceps or version in the flat pelvis and version in the justo-minor above 7.5 centimeters; symphyseotomy below. Tarnier gives preference to premature labor as the method of choice in pelves above 8.6 centimeters, when it can be inaugurated at the beginning of the ninth month.

Such have been the varied degrees of pelvic contraction to which symphyseotomy has been applied; and though the conditions and circumstances of the individual case will determine our choice of method, we must be guided to some extent by the results of the various operations resorted to in those intermediate forms of pelvic contraction for which symphyseotomy is advocated, and it is well to bear in mind that in these cases the mortality from forceps version and premature labor is not a low one, but greater than from the pubic operation.

The high-forceps operation is reported by Zweifel with a mortality of 7.3 per cent. The Dresden clinic from 1889 to 1894 records a maternal mortality of 5.17 per cent., and a fetal mortality of 21 per cent., 5.6 per cent. due directly to the operation; this with a conjugate down to 7.5 centimeters. Version in this class of cases, to a conjugate of seven centimeters in the flat and 7.5 centimeters in the justo-minor pelvis, gives a mortality of ten per cent. (Leopold).

Premature labor is practically without danger to the mother (perhaps one per cent.) when the operation is performed, as it usually is, by an experienced obstetrician; but the fetal mortality is great (40 per cent. in the cases reported by Tarnier, with a conjugate between 6.6 and 8.8 centimeters); and of these children born before the ninth month few survive the first year unless well cared for and favorably situated.

Craniotomy gives a mortality of perhaps five per cent.; Cæsarian section fourteen to twenty per cent.; and symphyseotomy, at the utmost, not over eleven per cent.—we may say, from two to eleven per cent.

The safety or danger of an operation is a patent argument for or against; and since symphyseotomy and the relative Cæsarian section as now advocated apply to the same moderate disproportion between fetal head

and maternal pelvis, to a similar class of cases, it may be well to note the relative mortality of these operations more carefully.

The lowest mortality of Cæsarian section is fourteen per cent., and that by only one operator, Sängér, in a small series of cases about equal in number to the symphyseotomies reported by Zweifel without a single death; even the mortality of the 303 cases collected by Harris, a total from all countries in 1895, is only eleven per cent.

Such are the results, as they have been obtained in cases taken as they come, one and all, not selected, none expunged, very much more favorable for mother and child than similarly collected Cæsarian sections, and more favorable even than small series by expert operators. Whilst those facts have but a very relative value, we cannot entirely ignore them.

The operation is decidedly less dangerous than Cæsarian section, and at least equally safe and more certain than forceps or version in the shorter sacro-pubic diameters. It is hardly more serious than premature labor in a pelvis from 7 centimeters to 8.5 centimeters, and far more promising for the child.

Yet we are loth to adopt symphyseotomy, especially as compared to the relative Cæsarian section; it is not so brilliant and impressive an operation and does not appeal to the surgeon of to-day as so strictly surgical. But we must accept that procedure which promises the greatest benefit to our patient with

least danger to herself and child. Then we must consider, not alone the great centers, the hospitals, but the country at large; and pubic section is of far more general usefulness, as it is not confined to such an extent as the Cæsarian to the surgical teacher or to the hospital and its trained staff. In fact, the first successful operation in this country, followed by others at a later day, was performed by a young practitioner in Texas.

Symphyseotomy is eminently adapted to the more trying conditions met with in everyday practise, successful especially as an operation of necessity after forceps have been tried and have failed, when Cæsarian section is very unpromising. Whatever experience may henceforth teach or our preference dictate, with moderate disproportion between head and pelvis—not over two centimeters, with pelvic contraction not below seven centimeters ( $2\frac{3}{4}$  inches)—pubic section is to be considered and is our only resource after an unsuccessful trial of forceps if the child is to be saved, replacing the brutal craniotomy of former days; and for the present we must accept such failures of forceps with moderate disproportion of head and pelvis as an absolute indication for symphyseotomy, for which we should always be prepared in the lesser degrees of pelvic contraction.

#### ON THE TREATMENT OF SOME OF THE MORE COMMON EYE AFFECTIONS.

In the *Edinburgh Medical Journal* for October, 1897, Mr. BERRY in an article on this subject, after discussing the general subject of conjunctivitis, shows that chronic conjunctivitis is met with in all degrees of severity, from what is little more than slight hyperemia of the conjunctiva to a greatly thickened, flesh-looking, pus-secreting state of that membrane, with incrustation of the lid margin; and often, too, owing to deeper infiltration, the palpebral fibers of the orbicularis fail to keep the lower lid properly in contact with the eye. The swollen conjunctiva thus becomes everted, and the excretion of tears is interfered with. The overflowing tears cause excoriation of the skin, and the ectropion once set up becomes more and more marked as time goes on. The everted conjunctiva, besides being thickened, is, as the result of constant exposure to the air, also hardened, and may even be incrustated or covered with scales or scabs.

These very bad cases of chronic conjunctivitis are mostly met with in old people of

uncleanly habits; they are not the cases one is most frequently called upon to treat.

In all cases in which conjunctivitis has become chronic, the first points to be ascertained, before any line of treatment is begun, are the nature of the external surroundings and of the treatment which has already been adopted. Where the patient is constantly subjected to smoky or hot and close atmospheres, or to any evident source of irritation, such conditions should, as far as possible, be removed. If he has been poulticing, or, what comes to the same thing, keeping moist applications to the eye, or tying it up and allowing the bandage to become moistened by tears, or if strong astringent lotions have been used, such treatment should at once be discontinued. It is generally well, too, to look to the state of the mucous membrane of the nasopharynx, as a chronic catarrh in this situation is apt to keep up a conjunctivitis, even although it may not have been the principal cause in originating it. Still more important in this respect is the state of the tear sac. Inflammation of the mucous membrane lining the tear duct and sac is not infrequently complicated by conjunctivitis, which is then generally set up by inoculation from this source. On the other hand, even severe purulent primary inflammation of the conjunctiva seldom, if ever, spreads to the tear sac. A proper treatment of the inflammatory condition of the nasopharynx is often useful, in addition to anything which may be undertaken for the more direct treatment of the conjunctivitis. But treatment of the sac for a coexisting blenorrhea is an absolute necessity. Without an improvement in this situation no treatment of the conjunctivitis alone can be of much avail.

In the least severe cases of chronic conjunctivitis, in which there is little or no thickening of the conjunctiva, and not much increase in the secretions, it is not generally necessary, if the precautions referred to as to surroundings be taken, to do anything very active. It is mainly in respect to their origin, namely, a preceding acute attack, that they differ at all from cases which the writer has described as conjunctival congestion. They should therefore be treated much in the same way. Change of air, especially to some dry, high-lying inland place, may be tried, and any existing error of refraction should be corrected. In addition, a weak astringent may sometimes be useful, such as solutions of hazeline, tannic acid, myrrh, alum, cinchona, or ichthyol.

The following are prescriptions which may be recommended for this purpose:

- ℞ Hazeline, 4 ounces;  
Aque carui, 8 ounces.
- ℞ Acidi tannici, 6 or 12 grains;  
Sodæ biboratis, 3 drachms;  
Glycerini, 6 drachms;  
Aque camphoræ, ad 12 ounces.
- ℞ Tincturæ myrrhæ, 2 drachms;  
Aque destillatæ, 12 ounces.
- ℞ Alumnis, 10 or 20 grains;  
Aque rosæ, 12 ounces.
- ℞ Extracti cinchonæ flavæ liquidi, 48 minims;  
Acidi hydrocyanici diluti, 15 minims;  
Glycerini, 6 drachms;  
Aque destillatæ, q. s. ad 12 ounces.
- ℞ Ichthyol, 1 drachm;  
Aque sambuci,  
Aque destillatæ, 3â 6 ounces.

In more severe cases, with thickening of the conjunctiva, swelling of the folds and deeper infiltration, as evidenced by slight ptosis, and with more or less distinct mucopurulent secretion, there is, Berry believes, nothing better than lead. A solution of the neutral subacetate of lead, in the strength of ten grains to one ounce of water, may be painted directly over the mucous surface of the everted lids once daily, and an irrigation of boracic acid made twice or thrice daily, or a wash of the same lead salt in weaker solution (one to two grains to the ounce of water) may be used about three or four times in the twenty-four hours. In the worst cases, painting with strong chlorine water or a two-per-cent. solution of nitrate of silver once daily is useful in addition to the lead wash. Where there is ectropion of the lower lid, the lower canaliculus should be slit with a Weber's knife. The scales must also be removed from the lid margin, and an ointment of iodoform and vaselin (1 to 5) smeared on the raw surface.

Owing to the frequency of folliculosis in young people, it often happens that the appearance of the conjunctiva presented in an ordinary mucopurulent inflammation is such as to suggest some different specific type of conjunctivitis. The overgrowth of adenoid tissue may be so marked a feature that the follicles appear as numerous papillæ in the swollen and congested membrane. When this is the case it is not uncommon to hear the conjunctivitis spoken of as a follicular conjunctivitis. It is not improbable that the same irritation which causes the conjunctiva to inflame may give rise to some further follicular enlargement, but, as far as the inflammation goes, both in its causation and course, it is a simple conjunctivitis. The treatment

should be in every way the same as that already described. Special care, however, is required in irrigating, as the presence of the many elevations makes it more difficult to thoroughly remove the secretions.

#### THE SURGERY OF THE STOMACH.

EWALD, of Berlin, read before the recent International Medical Congress a paper on this subject, which his large experience renders of great interest. The prognosis of operation upon the stomach has definitely improved, although there is still a marked difference between the results as reported by surgeons and physicians. He has had under observation in the past two and a half years twenty-nine cases of gastro-enterotomy, seventeen cases of resection, and twenty-two cases of gastrotomy. In most of the cases the condition dealt with was carcinoma, but there were three cases of benign stricture of the pylorus. In all but the three cases the immediate operative result was perfect. The following were the final results: 26 gastro-enterotomies, with 16 deaths, or 62 per cent.; 13 resections, with 9 deaths, or 69.2 per cent.; and 22 gastrotomies, with 12 deaths, or 54 per cent. mortality. These results are more unfavorable than those reported by surgeons, especially those from Mikulicz's clinic. But the surgeon, says Ewald, often regards a survival of the operation as a cure.

The limitations of the indications for operation, which are very variable, cause the statistics to vary; for example, the exclusion of manifestly unfavorable cases, which improves the statistics. The principal reason for failure lies in conditions which are beyond the surgeon's control. Cases often present insurmountable difficulties.

For the prognosis the following factors are important: (1) the position of the tumor on the stomach wall and the extent of surface involved; (2) the extent of metastatic involvement of other organs; (3) the extent of cachexia and consequently diminished powers of absorption and assimilation after the operation. Before opening the abdomen one can form no idea of the position and relations of the tumor. The so-called early diagnosis of carcinoma by analysis of the gastric secretion has not proved of value. The increase in the lactic acid appears, as a rule, later than the time the tumor first becomes palpable. Without the palpable tumor the diagnosis can only be extremely doubtful. We operate earlier at present than formerly, only be-

cause we make up our minds to operate, as a rule, sooner. The possibility of early operation depends entirely upon early recognition of the tumor. Gastrotomy is little more than a method of producing euthanasia. Cases of carcinoma of the esophagus should be supported as long as possible by feeding through esophageal tubes or per rectum, and gastrotomy attempted only when the body weight begins to diminish to the danger point.

In cases which apparently present favorable conditions for operation the prognosis is always doubtful, and interference should be advised only with a full understanding of this fact. The prospects of a cure are hardly twenty-five per cent., and of improvement not more than fifty per cent.

For every possible reason cases which seem favorable should be brought to operation at the earliest possible moment.—*Boston Medical and Surgical Journal*, Oct. 14, 1897.

#### REMARKS UPON THE NON-OPERATIVE TREATMENT OF CHRONIC SUPPURATIVE DISEASE OF THE ANTRUM AND VAULT OF THE TYMPANUM.

Dr. BUCK, the well known otologist and editor, contributes to the *Medical Record* of September 25, 1897, some of his views on this subject. As he well points out, recent otological literature is full of treatises which deal with the subject of new operative methods for the cure of chronic suppurative processes in the vault of the tympanum and the mastoid antrum. Of these operations ossiculectomy (for those cases in which the disease is limited to a small area within the tympanum) and the so-called Stacke's operation (for those in which the antrum is also involved) are the two representative types. It is not necessary here to enter into any further details regarding these operations or to discuss their relative merits. Suffice it to say that both of them have passed the probationary stage and are now generally accepted by otologists as safe and effective surgical procedures for the cure of the pathological conditions referred to above. Conceding, therefore, the value and the safety of these operations, the writer is nevertheless disposed to believe that they are resorted to in many cases in which the simpler cleansing methods would be found quite as effective in curing the disease. This remark has reference mainly to cases which are seen in private practise. In the treatment of infirm patients it is not often possible in our large-

cities to devote at least half an hour twice or three times a week to a single case; and, furthermore, experience in New York has shown that infirm patients cannot be depended upon to attend the institutions regularly for treatment. But unless these cleansing procedures are carried out in a minute and painstaking fashion, and at rather frequent intervals (two or three times a week), at best only a temporary amelioration of the disease will be secured. The writer is satisfied, therefore, that in dealing with this class of patients the otologist is quite right in urging the operative rather than the non-operative mode of treatment. In private practise, however, the conditions are quite different. The surgeon can give to this class of cases all the time that may be required, and the patients themselves can be depended upon to be regular in their attendance. Then again many private patients object strongly to being subjected to an operation which requires the use of ether or chloroform as an anesthetic, and which may keep them confined to bed or to the house for several days. It is natural, therefore, that these individuals, when the situation is laid before them, should prefer to have the cleansing or non-operative method of treatment tried first. It is not in every case, however, be it clearly understood, that we can safely offer this choice to the patient. Symptoms may have already developed which point to an extension of the disease to important neighboring organs, and in that case we must recommend strongly the more radical plan of treatment by operation—either Stacke's or the regular mastoid operation. But in most, if not all, of the cases in which a simple ossiculectomy is performed, and in quite a large proportion of those operated upon by Stacke's method, no such threatening symptoms exist, and consequently we are at liberty to deal with the problem before us in a more leisurely manner. If in such cases the opening in the tympanic membrane through which the pus and other products of the disease escape into the external auditory canal is fairly large—say two or three millimeters in diameter—and particularly if it occupies a high position, there can be no question about the propriety of giving the cleansing method a fair trial. On the other hand, if the opening is small—perhaps not more than a millimeter in diameter—or if it occupies a low position, the simple cleansing method is more likely to fail. But even here a limited myringectomy may suffice to overcome this drawback and so place

these cases on a par with the others. If, however, the pus finds an outlet through the *membrana flaccida*, it is better to proceed at once to an ossiculectomy (including, of course, a myringectomy). The necessity for a Stacke's operation or for a mastoid operation in this class of non-urgent cases becomes clear when both the cleansing method and a simple ossiculectomy (including the anvil as well as the hammer) have proved unsuccessful in arresting the foul-smelling discharge.

As regards the details of the cleansing method it is enough to state here that it consists essentially of only two steps, viz., the removal, chiefly by mechanical means, of all granulation tissue, cast-off epithelium, and detritus from the diseased tympanic cavity or antrum, and the destruction by chemical means of all pathogenic germs. Injections of hydrogen dioxide through variously curved glass tubes play a very important part in the procedure, not simply on account of the germicidal action of this fluid, but largely because the active effervescence, which at once takes place when it comes in contact with decomposing organic material, aids in dislodging the obstructing substances. When once the cavity has been cleared of all these and rendered aseptic, powdered iodoform or one of the more recent antiseptic powders (euphen, aristol, etc.) should be introduced in liberal quantity and allowed to remain there indefinitely. This, in brief, is the mode of treatment which the author terms the cleansing method.

In conclusion, he bears further testimony to the beneficial results which are obtained from the faithful and persistent employment of this method. In the majority of the cases treated in this manner the results have been successful, and he bases this belief not simply upon his own personal experience, but also upon that of other otologists with whom he has had an opportunity to compare notes.

---

#### NATURE AND TREATMENT OF MENIERE'S DISEASE.

In an editorial in the *Boston Medical and Surgical Journal* of September 30, 1897, after discussing the causes of Ménière's disease, the writer says:

"As for the treatment of this disease, that by large doses of quinine (for which we are indebted to Charcot, who first formulated it from theoretical considerations) is now the most in favor, at least in the French hospitals. It has been a matter of frequent ex-

perience since Charcot first published the remarkable results which he had himself obtained from this remedy that full doses of sulphate of quinine administered every day for two or three weeks produce a positive amelioration of all the symptoms. During the first few days of the treatment the head symptoms (the tinnitus and the vertigo) are worse, and the vertigo is so intense that the patient must be kept in bed to avoid the falls which he otherwise might receive. The medicine, too, is likely to upset the stomach, so that Gilles de La Tourette advises to prepare the patient by a milk diet before commencing the quinine treatment. It should be the aim to give the patient from seventy-five centigrammes to one gramme (ten to fifteen grains) during the twenty-four hours. This may be given in divided doses, or one-third of the daily quantity well diluted in water after each meal. At the end of eight or ten days the vertigo and tinnitus diminish, in many cases to completely disappear after a few days more of treatment.

"Naturally many obstinate cases are only benefited, not cured, and in all a frequent return to the remedy after a period of suspension is necessary."

#### IRRIGATION IN INTUSSUSCEPTION.

In the *Intercolonial Medical Journal of Australia* of June 20, 1897, A. JEFFREYS WOOD, after detailing a number of cases of intestinal obstruction successfully treated by irrigation, points out that before attempting to reduce an intussusception with water sufficient assistance must be secured: first, an anesthetist who must watch his patient carefully; second, an assistant to keep the funnel full and at the required height; and third, another assistant who will raise the buttocks, hold the tube in position, and prevent the water escaping from the anus. This leaves the surgeon free to watch and gently manipulate the abdomen. It is possible to manage with an anesthetist and one assistant, but the second assistant is of great value if available. The child is of necessity exposed a good deal during the treatment, so that a hot-water bag to lie on, with cotton-wadding coverings for the legs, are necessary to prevent too much shock. The height at which the funnel or irrigator has been held in these cases has been about four feet.

Power, in his recent lectures, mentions the experiments made by Mortimer and Mole on the pressure that the colon will successfully

resist after death. It was concluded from these experiments that a column of water eight feet in height usually ruptured the bowel. On referring to Starr's Text-book on Diseases of Children, it will be found that Ashhurst, of Philadelphia, recommends that the funnel be held as high as eight feet in children, and twenty feet in adults. One American writer relates the reduction of an intussusception where the funnel was carried to the top of the stairs, while the child was on the ground floor. It seems from the American work that the bowel during life is more resistant than it is after death. Safety lies in moderation, and anything from two and a half to four feet will, as a rule, be found quite sufficient pressure to reduce most cases of intussusception.

The presence of a swollen condition about the ileocæcal valve after reduction must not be mistaken for an unreduced intussusception. After trying reduction by hydrostatic pressure, a reasonable time should be allowed to elapse before proceeding to abdominal section, for after recovery from chloroform all the symptoms of obstruction will quickly manifest themselves if the reduction has not been completed. Bilton Pollard relates a case in which he performed an abdominal section after irrigation because a swelling remained in the right iliac fossa. The intussusception was found to have disappeared, but the ileocæcal valve was the site of considerable swelling.

Reduction by air alone is frequently successful, and should be tried in the absence of an irrigation apparatus. Higginson's syringe, the common bellows, or a bicycle pump may be used to effect this purpose, but to attempt the reduction without an anesthetic would be only to court failure.

The tendency that intussusception has to recur after reduction has often been mentioned. One case attending the Children's Hospital three years ago recurred three times in a week, and was finally cured by irrigation without recourse to abdominal section. Many surgeons who advocate laparotomy for intussusception recommend that the operation should be performed early if it is to be successful, but these early cases can be reduced by simpler means, and it is with a view of drawing attention to the success of these means that the writer publishes his cases.

[The hydrostatic pressure recommended by some authors as quoted above is excessive and dangerous. A pressure of two to three feet is sufficient and much more safe.—Ed.]

*THE TREATMENT OF CEREBRAL HEMORRHAGE.*

In a recent issue of *Treatment* BYRAM BRAMWELL, so well known for his able studies in clinical medicine, gives directions for the treatment of this alarming condition. He thinks that at the commencement of an attack of cerebral hemorrhage the first indication for treatment is to try and arrest the bleeding and limit the extravasation. We should try to carry this indication into effect by employing measures calculated to lessen the activity of the cerebral circulation.

The head and shoulders should be raised rather than lowered, an ice-bag should be applied to the head, warmth applied to the feet with the object of dilating the peripheral vessels, leeches may be applied behind the ear, and a drop or two of croton oil administered with the object of producing a brisk watery evacuation. Venesection, bleeding from the temporal artery, compression of the common carotid artery, and ligaturing the carotid artery, on the side of the hemorrhage, are other methods which have been recommended.

The value of bleeding (either from a vein or the temporal artery) has been much debated; the author believes it to be useful and especially indicated in those cases in which the face, head and neck are turgid, the pulse hard, full, and slow, and the left ventricle hypertrophied. Bleeding is contraindicated in those cases in which the pulse is feeble, rapid, or irregular, the heart dilated or weak, and the patient very old or debilitated.

The author has no experience of compression of the carotid, a method of treatment which has been recommended by Professor Victor Horsley.

A brisk watery purge acts in very much the same way as a moderate bleeding, but for the production of a brisk watery purge time is required. Consequently in many cases venesection is preferable. In those cases in which the advisability of bleeding is doubtful, a drop or two of croton oil and an enema may be administered.

The common practise of applying a blister to the nape of the neck is of doubtful advantage. It is extremely doubtful if at this stage of the attack counter-irritation does any good. In the severe cases it is useless, and in the slight cases in which the coma is speedily recovered from it is unnecessary (even if it were beneficial), and it may be a source of discomfort to the patient. If a blister is to be applied at all it is probably

best applied to the shaved scalp between the ears (*i.e.*, over the top of the head). The ice-bag, which he considers of far more importance, may be applied over the top of the blister.

If there is retention of urine, the bladder should be emptied by the catheter at regular intervals. If there is incontinence, the nurse should see that the patient is kept dry and clean; this is a most important point, for the development of a bed-sore is one of the chief dangers in cases which do not prove immediately fatal.

It is doubtful if any internal remedies have much influence in arresting the bleeding. Ergot has been recommended for this purpose. Nitrite of amyl, or nitrite of sodium, is perhaps useful in some cases in which the pulse is hard and tense, but venesection is probably a better remedy. Aconite has also been recommended in those cases in which the pulse is full and bounding.

In those cases in which the coma is gradually becoming deeper and deeper, the pulse (though perhaps full and bounding or hard) slower and slower, the respiration more and more affected—in short, in cases in which the intracranial pressure is evidently steadily increasing as the result of a gradually increasing hemorrhage—the advisability of trephining and tapping the hemorrhagic cavity and so preventing rupture into the lateral ventricles—an event which is certainly and rapidly fatal—should be considered. Such cases are comparatively rarely met with.

The second indication is to attend to the condition of the bladder, and to take means to prevent if possible the formation of a bed-sore. The patient should be placed at once, or as soon as he can be removed without risk, upon a water bed. Care must be taken, too, that the hot bottles which are applied to the feet are not too hot. Owing to the comatose or semi-comatose condition the patient will not of course make any complaint (the nurse has, under such circumstances, to feel for him), and owing to the diminished trophic resistance of the skin, a degree of heat which would not be prejudicial to a healthy person may easily blister and burn the skin of a patient suffering from cerebral hemorrhage.

The third indication is to sustain the vital powers by appropriate feeding, and if necessary by the administration of cardiac tonics and stimulants. It is important to avoid giving anything which is likely to produce vomiting, for the straining which attends the

act of vomiting may reopen the ruptured vessel, or, if the bleeding is still going on, increase it. For the same reason stimulants should be withheld, unless they are absolutely required. If the heart is failing, and the pulse rapidly running down, stimulants must of course be administered even at the risk of increasing or reexciting the hemorrhage.

During the comatose state the administration of food and liquid by the mouth requires to be conducted with great care and caution.

A nutrient enema may be given every four hours, and if necessary it may be supplemented every now and then by a nutrient suppository.

It is unnecessary to say that in those cases in which the sphincters are relaxed rectal feeding cannot be satisfactorily carried out.

During the stage of coma, mucus, saliva, etc., are apt to accumulate in the mouth and pharynx, and to add to the difficulty of the respiration and the tendency to death from asphyxia; for it must be remembered that in some cases the patient dies during the stage of coma from failure of the heart's action, in others from asphyxia and failure of the respiration, in others from the two conditions combined. In others, again, death is preceded or attended by hyperpyrexia.

By attention to position (turning the patient on his side, turning the head to one side, etc.) it is in many cases possible to avoid the accumulation of mucus, etc., at the back of the throat and so to diminish the risk of asphyxia. The relief is, however, in most cases merely temporary. In cases of cerebral hemorrhage in which these conditions are developed the result is almost always fatal. It is very different when we are dealing with the status epilepticus. In that condition the author has undoubtedly in more than one case, by preventing the accumulation of mucus, saliva, etc., in the back of the throat, and so preventing asphyxia, saved the life of the patient.

Provided that the patient can swallow, a teaspoonful or two of milk may from time to time be given by the mouth, but once the bowels have been thoroughly well opened it is better to feed the patient by the rectum. If there is difficulty in swallowing, if the administration of fluids by the mouth produces coughing or choking, the feeding should be entirely rectal. Alcoholic stimulants, digitalis, etc., may be given by the same channel, or strychnine (a drop or two of the liquid every two hours) may be administered hypodermic-

ally, the effect being of course carefully watched.

Possibly in some cases in which the respiration is much embarrassed and death from asphyxia seems imminent, oxygen inhalations might be beneficial.

The main objects of treatment during the first stage of cerebral hemorrhage are, then, to arrest the bleeding and to tide the patient through the stage of coma.

If the patient recovers from the stage of coma, the next object is to prevent and allay the secondary cerebritis.

As the patient recovers from the coma absolute rest should be enjoined. A little liquid food (milk) and water may be given by the mouth; the rectal feeding may be still continued; great attention must still be directed to the condition of the bladder and rectum and to the prevention of bed-sores.

At this stage of the case the author has usually commenced the administration of iodide of potassium—five grains three times daily.

When symptoms indicative of secondary cerebritis (a rise in temperature, headache, muscular twitchings, rambling, a return of the coma, etc.) develop, a brisk purge may be again administered, cold (an ice-bag) re-applied to the head, and bromide of potassium or a combination of bromide of potassium and chloral hydrate given in addition to the iodide.

If during the stage of secondary cerebritis the pulse becomes very quick, feeble, or intermittent, cardiac stimulants—digitalis, strophanthus, strychnine, etc.—must be given; alcohol is probably better avoided. If the pulse tension is high the administration of remedies which depress the force and violence of the heart's action, such as aconite or nitrite of sodium, may perhaps be employed with advantage in some cases in addition to purgation.

As the symptoms of secondary cerebritis subside, the bromide of potassium and chloral hydrate should be discontinued.

After the symptoms indicative of secondary cerebritis pass off, complete rest must still be enjoined until the acute changes around the clot have subsided. The iodide of potassium, with perhaps a small dose of carbonate of ammonium, or tincture of nux vomica, should be continued. During this, the early, stage of convalescence the patient must be carefully fed, the condition of the bladder and rectum attended to, and any cystitis or bed-sores which may have developed treated. At this

stage of the case gentle massage is useful. Faradism of the paralyzed muscles, strychnine, and too active attempts at voluntary movement of the paralyzed parts, all of which may be most useful a little later, should be avoided, or if employed, administered with great caution.

Some authorities recommend the application of the constant electric current to the head—one pole being placed just above either mastoid process. The constant current, by its catalytic action, is supposed to aid the absorption of inflammatory products and to promote the nutrition and restoration of the damaged nerve elements. It is very doubtful if electricity applied in this way is of any real use. If it is employed the greatest care should be taken to use a weak current, and the effects which the current produces on the patient should be carefully watched.

In severe cases of hemiplegia the tendency to the development of contractures should be remembered, and passive movements (more especially of the fingers, wrist, and elbows, for it is at these parts that the contractures are most apt to be developed) carefully and diligently practised.

When there is reason to suppose that the acute changes have subsided—*i.e.*, at the end of six weeks or two months—the treatment appropriate for an ordinary case of hemiplegia may be employed. A more liberal dietary may be allowed; the patient should be encouraged to practise systematic voluntary movements; general tonics, such as quinine and small doses of strychnine, may be given internally; and massage and electricity judiciously and cautiously applied to the paralyzed muscles. It is difficult, the author thinks, to overestimate the value of frequently repeated and systematic voluntary efforts in cases of hemiplegia, and indeed in all forms of paralysis.

The treatment (amount of exercise, etc.) must of course be carefully and judiciously regulated in accordance with the conditions which are present in each individual patient (the severity of the paralysis, etc.), the state of the heart, kidneys, etc., being taken into account.

If the exaggerated myotatic irritability (spastic condition, exaggerated reflex action) which is usually developed is excessive, dilute hydrobromic acid, bromide of potassium, etc., may be administered; in these cases strychnine, nux vomica, and the faradic current are usually better avoided. It is in those cases in which the muscular atrophy is considerable

that electricity and strychnine are most useful. In many cases in which muscular atrophy and myotatic irritability are combined a combination of dilute hydrobromic acid or bromide of potassium with strychnine or nux vomica is, he thinks, useful.

It has been shown that in the ordinary form of cerebral hemorrhage (that due to miliary aneurisms and high blood-pressure in the arterial system, cirrhosis of the kidneys, etc.) it is practically certain that if the patient lives sufficiently long and is not cut off by some other disease or intercurrent complication, a second attack of cerebral hemorrhage will sooner or later occur. A great deal, however, can in many cases be done to prevent and defer a second rupture. Everything which is likely to act as an exciting cause should so far as possible be avoided. It is especially important to reduce the blood-pressure when the pulse tension is excessive, and to avoid everything, such as sudden efforts, mental excitement, sudden exposure to cold, straining at stool, etc., which is apt to produce a rapid rise in the intracranial blood-pressure. A patient who has had an attack of cerebral hemorrhage, however slight, should lead a quiet, routine life; he should be made to realize that he is not the man he was before. If he is a business man, more especially if his business entails much bodily exertion, mental strain, or excitement, he should be advised to give it up if he can by any possibility do so. An attack of cerebral hemorrhage, however slight, is a danger signal which cannot be ignored. Work which entails active exercise, bodily exertion, or mental strain and excitement is in such cases dangerous. The author makes this statement advisedly, well knowing that in many cases it is a mistake to advise a patient to give up his life's work. Some people are only happy so long as they are at work. Some men if advised to give up a busy and active existence for a life of idleness and humdrum routine, more especially if they have no hobbies or sources of recreation to fall back upon, are miserable. In such cases it is usually preferable to allow the patient to continue to work, perhaps in a modified way, than to worry in his idleness. Each case must be judged of on its own individual merits; the temperament of the patient and the nature of the disease have to be carefully considered; the risks entailed by the work and the risks entailed by his idleness and want of occupation have to be weighed one against the other. But after an attack of

cerebral hemorrhage there is in most cases little or no choice.

The diet should be light and nutritious; if the patient is gouty, if his kidneys are cirrhotic, if his blood-pressure is high, a non-nitrogenous diet is best; in such cases iodide of potassium, salicylate of soda, etc., may be given internally. In these cases, and in fact in almost all cases in which a cerebral hemorrhage has occurred, alcohol should be prohibited. A certain amount of tobacco, however, may be allowed. Care should be taken that the skin and bowels functionate regularly and actively. The patient should be well clothed. He should not be allowed to suddenly expose himself to cold, more especially after being in a warm atmosphere. When the arteries are atheromatous special care must of course be taken to avoid any sudden exertion or strain. The amount of exercise which the patient should be permitted to take depends, of course, upon circumstances. So far as the condition of his general health is concerned, a certain amount of gentle, walking (outdoor) exercise is beneficial; but sudden exertion, running for trains, straining at stool, etc., anything which produces overfatigue, anything which places a sudden strain on the cerebral vessels—and in this connection mental agitation and excitement is probably quite as prejudicial as too violent physical exertion—should be rigidly avoided.

#### LARKSPUR POISONING IN CATTLE AND SHEEP.

From the observation of several cases of larkspur poisoning which happened in Montana early in the spring, says Dr. M. E. KNOWLES, the State veterinarian, at a time when the blossoms and seeds had not yet been produced by the plants, there seems to be no doubt that the poisonous principle in larkspur is distributed throughout the whole plant (roots, leaves, flowers, and seeds), and therefore poisoning may occur at almost any time during the life of the plant. A number of serious and extensive losses among both cattle and sheep have come under his observation in Montana during the past three months, the most serious among sheep. He ascertained upon close investigation that cattle and sheep were most likely to eat the plant and become poisoned when they were on a range short of grass, or when turned immediately into a locality while hungry and in a condition to eat any plant in sight. The common symptoms of poisoning in sheep and

cattle are manifested first by the animal straying behind the herd and appearing dull and indifferent to its surroundings, but if suddenly startled it will walk in a directly straight line until it meets some obstruction, when it probably falls, makes but few struggles, but lies remarkably quiet under the influence of the poison. There is rarely any bloating, but in nearly all cases there are dribbling of saliva from the mouth, champing of the jaws, and frequent attempts at swallowing.

The treatment most successfully applied has been by pouring water of ammonia on to a rag or sponge and holding the same to the animal's nose until it fully inhales the fumes of the ammonia; it is sometimes necessary to pour five or six drops of ammonia into the nostrils. The administration every ten or fifteen minutes to sheep of a teaspoonful of ammonia water in half a cup of water, and the administration of alcohol (in tablespoonful doses) diluted with three times this quantity of water, every fifteen or twenty minutes, will be found beneficial when ammonia does not promptly relieve the animal. Where it is possible, and the drug is accessible, a hypodermic injection of a sixtieth of a grain of atropine sulphate to sheep and one grain to cattle will bring about a cure or relieve the poisoning in a rapid manner, often reviving them when they are apparently beyond help. Digitalis and tincture of nuxvomica in small doses are also useful and frequently bring about a cure very promptly.—*New York Medical Journal*, Aug. 21, 1897.

---

#### ON THE USE OF SULPHATE OF QUININE IN THE TREATMENT OF INCOMPLETE ABORTION.

SCHWABE, in a paper published in the *Medical Chronicle* for July, 1897, says the treatment to be adopted in cases of incomplete abortion is still a matter for discussion. Some writers advise an expectant plan with rigid antisepsis of the vagina, unless the symptoms of hemorrhage or infection supervene, in which instance the uterus must be evacuated at once. Others, on the contrary, consider that placental retention, partial or complete, is always a dangerous condition, and are in favor of immediate intervention in every case of incomplete abortion. The author considers that, in the vast majority of cases, it is wise to evacuate the uterus as early as possible. He then proceeds to discuss the various methods of emptying the uterus at our

disposal. He points out that uterine douches, tampons, and exploration of the uterus with the finger or curette are by no means free from risk. The principal drugs acting on the uterine muscle are ergot and quinine. The former is, however, hardly advisable, as it tends to cause contraction of the cervix and retention of products *in utero*.

Sulphate of quinine is considered by Schwabe to possess a distinct "oxytocic" action. It produces intermittent uterine contractions resembling the physiological ones. It does not, however, appear to possess the power of initiating uterine action, and will not produce abortion unless uterine contractions have previously commenced.

In this paper Schwabe gives the results of seven cases of incomplete abortion treated by the administration of quinine. In every case the placenta was expelled spontaneously, at intervals varying from half an hour to fifteen hours after receiving the dose—the average time was four and a half hours. In three cases the placenta had been retained three to four days, and in each instance was expelled in a few hours.

The dose is fifteen grains, given in two portions of seven and a half grains each, taken at ten-minute intervals. Usually within a short time uterine contractions, as shown by pain, are set up.

Quinine is by no means a new remedy for uterine atony, though opinions as to its usefulness have been very much at variance. The author acknowledges that in some of the cases no effects followed the administration.

Schwabe's conclusions are briefly as follows: (1) The retention of products in the uterus after abortion is serious, from the risks of hemorrhage or infection; steps should be taken to facilitate expulsion as soon as possible. (2) Digital or instrumental means may be inefficient or dangerous. (3) Sulphate of quinine has a definite stimulating effect on uterine contraction. (4) It is quite harmless; if it fails, other measures may then be adopted. (5) It should be prescribed if the placenta is retained six hours after the fetus, or earlier if hemorrhage is present.

In the discussion which followed the reading of this paper M. Cordes (Geneva) stated that he had used quinine in this condition for some time, and confirmed the views of M. Schwabe. It was pointed out, however, that to obtain reliable evidence as to its value, the cases in which quinine failed to act should also be recorded.

[The Editor has published an article in the GAZETTE during the current year which sought to prove that quinine does not possess any such oxytocic influence as relied upon by Schwabe.]

#### A STUDY OF THE PHYSIOLOGICAL ACTION OF HYDROCHLORATE OF EUCAINE.

In the *Bulletin of the Royal Academy of Medicine of Belgium*, No. 4, 1897, VER EECHE, after a full experimental study of the physiological action of hydrochlorate of eucaine, sums up the work on which he has been engaged as follows: (1) Hydrochlorate of eucaine in the frog determines successively excitations, convulsions, and paralysis; the latter is of peripheral origin. The return to the normal state is accompanied by convulsions, and later by hyperexcitability. The fatal dose is 0.16 grammes per kilogramme. (2) In the warm-blooded animals hydrochlorate of eucaine primarily produces excitation, which is followed by convulsions, and finally death from asphyxia occurs. There is no paralyzant dose. The fatal dose in the guinea-pig is from 0.049 to 0.052 grammes per kilogramme. There is no cumulative action of the poison; on the contrary, the organism may accustom itself to increasing doses of the drug. Cocaine has twice the toxic action which is possessed by eucaine. (3) Hydrochlorate of eucaine acts on the heart principally by paralyzing the intracardiac motor center; secondarily it alters the muscular fibers of the heart. (4) Hydrochlorate of eucaine lowers the blood-pressure by diminishing the peripheral resistance. (5) Hydrochlorate of eucaine directly stimulates the respiratory center in the medulla. The paralysis of the respiratory center in cases of fatal poisoning is not the result of the direct action of poison, but is due to asphyxia, which in its turn is caused by an excess of carbon monoxide in the blood. (6) Eucaine increases diuresis, accelerates nitrogenous, phosphorous, and chlorous metabolism; it produces glycosuria, but only during the presence of intense convulsions. (7) Hydrochlorate of eucaine does not appear to eliminate itself by the kidneys; on the other hand, it probably undergoes a chemical decomposition in the economy. (8) Hydrochlorate of eucaine, instilled in the conjunctival sac, first produces anesthesia of the conjunctiva, and finally of the cornea, at the same time that it rapidly lowers the intraocular pressure. (9) Hydrochlorate of eucaine

reduces the vitality of the red blood corpuscles and produces fatty degeneration of the heart and of the involuntary muscles. (10) Chloral hydrate diminishes or stops the convulsions produced by eucaine. Chloralization will allow the administration of doses of eucaine which are beyond the fatal limit. (11) The antagonism between hydrochlorate of eucaine and chloral hydrate is not reciprocated.—*International Medical Magazine*, August, 1897.

#### PAROXYSMAL TACHYCARDIA.

In a recent issue of the *Bristol Medical-Chirurgical Review* P. WATSON WILLIAMS contributes an article on this topic. After discussing the general aspects of the condition he states that in his opinion the results of treatment, on the whole, are eminently unsatisfactory in controlling or arresting the actual attacks. The writer has already remarked that in one severe case the only drug that in any way seemed to benefit the patient was digitalis, and that in other cases digitalis had given good results. Bouveret states that digitalis has proved of only moderate value. Oettinger, keeping his patient in bed, found the pulse improved and the quantity of urine increased under digitalis; but Pye-Smith has found digitalis and strophanthus "most disappointing in these cases. Absolute confinement to bed in the recumbent posture for a length of time led to a slowing of the pulse, and often to complete cure." Yet the author's own experience and a consideration of recorded views of others tend to the conviction that although digitalis has but a limited action in controlling or aborting the actual attacks, it is the most useful drug for improving the circulation in the intervals between the severe and prolonged attacks. When the mitral valve has become incompetent from secondary dilatation of the heart, when the urine is deficient in quantity and albuminuria has occurred, when anasarca supervenes and the respiratory function is embarrassed, then we shall find that digitalis in some form affords the best chance of restoring the failing circulation, and improving the heart generally.

Some have given morphine with advantage—at least, it sometimes calms the patient without cutting short the attacks. Oliver considered he had cured his patient with belladonna.

Caffeine, nitrite of amyl, and nitroglycerin have been tried with no result. Sometimes a

strong dose of brandy or whiskey stops an attack, and in Nothnagel's case the attacks were arrested by deep inspiration.

In several cases faradization of the vagi has been tried, and failed to have any effect; but pressure on the vagi in the neck, and in one case compression of the thorax, would stop the attacks. These proceedings have been tried in other cases, however, and failed.

It is important to attend to the general health, and especially to rectify any gastric disorder; anemia should be treated with iron and general tonics. Tea, coffee, smoking, undue exertion or excitement, and anything which tends to excite the nervous system, should be carefully avoided.

#### CHELIDONIUM MAJUS IN CANCER.

The *Chelidonium majus*, or tetterwort, is when given internally a drastic cathartic. Applied locally it is a strong irritant and has a reputation in the cure of warts and skin diseases. It has recently been tried in inoperable cancer of the uterus by certain German surgeons (who injected the extract into the cancer tissue with a syringe) and been rejected by them as useless.

In the *Centralblatt für Gynäkologie* of July 31 Dr. Frendenberg reports some not so unfavorable cases from the service of Dr. Landon. His method was to apply a fifty-per-cent. solution of the extractum chelidonii upon cotton wads, directly against the surface of the cancer mass or pressed into its hollows. This method had the advantage of being painless. He denies that it checks the inward extension of the cancer or prevents metastasis. He observed, however, that when pressed thus gently with a tampon against the cauliflower masses it softened them down so that their sites were transformed into craters. Moreover, as a result of the applications a very decided mitigation of the horrible odor was obtained. The hemorrhage from the cancer was also controlled by the application in some cases.

For dilution of the extract use weak antiseptic solutions. If the tampons so wetted are pressed hard in for the control of hemorrhage or the compression of vigorously growing masses, they must be changed by the doctor daily; otherwise a string may be attached by which the patient removes them next day, coming to the physician every third or fourth day, and irrigating herself in the interval.—*Maryland Medical Journal*, Aug. 28, 1897.

ON THE CUTANEOUS ABSORPTION OF  
IODINE, IODOFORM, AND IODIDE  
OF ETHYL.

In the *Bulletin Général de Thérapeutique* of May 15, 1897, LINOSSIER and LANNOIS, of Lyons, contribute a paper upon this subject, first pointing out that the application of tincture of iodine to the skin may be followed by the appearance of minute quantities of iodine in the urine; and they then quote Rabateau, Röhrig, Binz and others as responsible for this statement. The question arises, How does this absorption take place? Does iodine as a volatile body pass through the skin and enter the blood, or does it enter the system by its vapor being inhaled through the lungs? These authors have already proved in the case of guaiacol and salicylate of methyl that these substances pass through the skin with great ease. In the experiments which they carried out they applied these various iodine compounds in different ways to the skin, in some instances arranging the application in such a way that it was impossible for it to pass into the air which the patient breathed.

As a result of their studies the authors conclude that the earlier investigators were right in asserting that iodine is absorbed from the cutaneous surface, that it is not so actively absorbed if it can escape into the air as when it is confined to the skin by means of a bandage, and that the maximum absorption occurs immediately after its application. They also conclude that the local destruction or alteration in the skin which is produced by the application of the tincture of iodine does not interfere with absorption, but on the other hand distinctly aids it. The absorption of iodine from the skin, however, is so uncertain and irregular that this means of medication cannot be resorted to when we desire to influence the general system by this drug; neither can iodoform nor iodide of ethyl be used for this purpose, as the iodine which they contain is not absorbed in sufficiently large quantities from the skin to be of any value.

IMPRESSIONS OF A YEAR'S GYNECOLOGY  
IN GERMANY.

FOURNESS BARRINGTON in the *Australasian Medical Gazette* of July 20, 1897, summarizes his impressions in gynecology as follows:

As to vaginal hysterectomy he personally assisted at forty-three operations—twenty-five for carcinoma uteri, ten for pyosalpinx, four for myoma uteri, two for prolapsus uteri,

one for hyperplastic endometritis, one for chronic inversion of uterus.

From consideration of these operations, performed by various surgeons, the points that seem to command the best results were these:

1. Circularly incise vagina; define lower limit of bladder, and free it and ureters from uterus before attempting to place a ligature on broad ligament.

2. Open posterior cul-de-sac, and insert rolled sterilized gauze tampon to prevent prolapse of intestine into wound. Hemostasis insured by ligating together, and cutting in sections vagina and peritoneum circumscribing cervix.

3. Secure broad ligaments in sections by carefully prepared catgut ligatures tied very tightly, and in cases of carcinoma remove uterus by direct gradual traction rather than through posterior fornix, to prevent peritoneal contamination. The use of silk ligatures always leads to suppuration, and the process of tugging them away, which often has to be resorted to, has little to commend it.

4. Fix stumps of broad ligaments in angles of vaginal incision, and sew up completely rent in vaginal roof, using catgut, thereby dispensing with peritoneal drainage.

Certainly, no operation for fixation of a non-adherent uterus should be carried out until means directed towards endometritis, restoration of pelvic floor, and retention for some time in its proper position have proved futile.

Finally he submits the following views:

That when ablation of the myomatous uterus is undoubtedly called for, pan-hysterectomy is preferable.

Multiple fibroids, either edematous or cystic, and demanding abdominal section, will be best met by ablation of the appendages, when they are completely removable. Conservative methods in diseases of the appendages can with advantage in suitable cases be more frequently carried out by abdominal and vaginal section.

That in every gynecological operation the aim should be at a perfect aseptic technique, and to attain this object methods should be controlled from time to time by culture experiments.

That irrigation and drainage are valuable safeguards against sepsis and hemorrhage, and should be frequently resorted to.

That Trendelenburg's position is an immense help in intrapelvic surgery generally,

and a moderately free incision must be super-added.

That vaginal hysterectomy in carcinoma should be invariably complete, and that ligation of the broad ligaments with catgut, as being readily absorbable, and complete closure of the vaginal roof, with extraperitoneal treatment of the stumps, is the best procedure.

That the suprapubic route is preferable to vaginal hysterectomy for ablation of chronically diseased adnexa, which, if suitable for removal from below, should be dealt with by anterior colpotomy, with retention of the uterus, which is curetted and drained.

Anterior colpotomy is a valuable addition to surgery, but in the presence of dense adhesions laparotomy is preferable; but it is unlikely vagino-fixation of the uterus will retain a place in surgery.

---

#### THE TECHNIQUE OF INTRACRANIAL SURGERY.

TIFFANY presents an interesting contribution on intracranial surgery in the *Annals of Surgery* for September, 1897. Speaking of the difference between operations for traumatic and pathologic causes he says the two should be considered quite separately; indeed, comparison between them is almost impossible. In traumatic cases operation is undertaken as a matter of necessity, suddenly, perhaps with instruments not quite suitable, but certainly without delay, the condition of the patient not permitting it. There has been no previous preparation of the patient. His general condition is unknown. No preparatory treatment is possible. The elements of sepsis are often present, not only upon the surface, but perhaps thrust into the tissues by the traumatism for which the operation is undertaken, and infection may have already occurred within the head. The condition of the kidneys may be mentioned, as a matter of which the operator must be in ignorance; for even though the urine be examined immediately after the injury and before the operation is undertaken—and this should always be done—yet if the patient has been transported a certain distance in cold weather, or the skin surface has been largely uncovered, as is not unusual after an injury, albumen will generally be present, and possibly also casts may exist; and so an accurate knowledge of the condition of the kidneys is wanting. The details in operative work, also, are often obscure, and

landmarks obliterated, both within and without the skull. Finally, the head is opened, in traumatic work, as circumstances permit or seem to indicate. The head may have been already opened before the case is seen by the surgeon, who is forced to do patch-work.

In operations for pathologic conditions, on the other hand, the reverse of what has been said exists. The proper time is chosen; all things are prepared; the proper light obtained; asepsis is secured; there is a due regard for both local and general cleanliness; not only has the condition of the internal organs been investigated, but they have been made to work, and work smoothly; a well and carefully considered operative procedure is carried through after due study and consideration, and all things necessary are at hand. The operation then is undertaken in the best way for the patient's welfare. It is proper, therefore, to draw a hard and fast line between the results of operations undertaken for traumatic and pathologic conditions, not that excellent work is impossible in traumatic cases, but the very fact of the patient's having been subject to injury may take out of the surgeon's power the ability to obtain certain conditions which are essential to success, and should exist, but may not—cleanliness, for instance.

It is not easy to clean a head, and it is still more difficult to prepare a portion of a head and operate so that cleanliness shall obtain. It is best, therefore, that the whole head should be prepared and cleaned. This applies to all cases, unless of a very minor character.

In traumatic cases the head is to be shaved and the skin cleaned with green soap, hot water, nail-brush, and carefully scrubbed. The ears should be cleaned out and filled with sterile cotton. The eyes should be closed with pads of sterile cotton. The scrubbing should be done not only upon the surface, but, if a wound exist, it should be scrubbed likewise, and an effort made to get out any dirt which has been forced beneath the skin; punctured wounds should be laid open; tracks beneath the skin should be opened and scrubbed; the edges of irregularly bruised tissue may be trimmed away and a clean surface obtained. Where coal-dust or grease has been forced beneath the surface, scrubbing with a nail-brush and soap and washing with ether and alcohol will often be sufficient to obtain a clean surface. Dirt ground into the surface or edges of broken

bone can be scraped away, or nibbled away with forceps, so as to be gotten rid of. After cleansing the head for traumatic operations, a towel wrung out in corrosive sublimate solution, or sterile water perhaps, can be used as a cover for the prepared territory until instruments and other things are ready. In preparing a patient for an operation undertaken for some pathologic condition (not traumatic, of course) the author always prepares the patient a day before the operation, and then again just prior to operating, and sees no reason to depart from this habit. An alkaline solution, bicarbonate of soda, he has found useful to remove dandruff from the scalp, but he generally uses green soap. Shaving and scrubbing with green soap, or a poultice of green soap applied over the surface after shaving and left on for a couple of hours and then scrubbing afterwards, is efficacious. He removes the green soap with alcohol, then ether, and then has the clean scalp tied up in a corrosive sublimate solution until the following day; a repetition of the cleansing as already described gives a clean surface upon which to operate.

As the brain is to be covered in after the operation, a large osteocutaneous flap, the base turned towards the blood-vessels, is probably the most effective way of uncovering the brain. It should be cut in one piece and then broken at the base so as to permit of turning down. This breaking down at the base is much assisted by cutting across the bone with sharp forceps, or otherwise, and it should be so cared for during operation that the skin and bone are not torn asunder; it may be necessary to envelop it in a cloth wrung out in hot sterile salt solution. The cutting of the bone is to be done by the instrument with which the surgeon is most familiar—the trephine, rapidly revolving saw, chisel and mallet, all have their advocates. Jarring the head is probably the objection most frequently raised against the last mentioned tools. They are, however, the tools with which Tiffany is most familiar and which he prefers. Should the opening not be large enough in the skull, there should be no hesitation about cutting away the borders of the opening until sufficiently large. For this purpose rongeur forceps seem to leave little to be desired.

There is a difference between the sides of the skull and the top, for bone need not be put back in the temporal fossa, since, thanks to the dense temporal fascia, there is not much sinking in; it is otherwise at the top

and front of the skull, as bone there wanting results in a deep depression. The time which is consumed in exposing the brain is largely the result of the bone-cutting. Twice it has been the author's fortune to operate upon heads where, at previous operations, bone has not been replaced. It was very easy to open these heads, and the operation was done with great rapidity. It is therefore a matter to be thought over and carefully considered whether, when it becomes necessary to operate within the head, it may not be expedient to raise a large flap, remove the necessary bone, replace the flap, and allow it to heal. A month or two afterwards the surgeon will operate to remove the pathologic condition present, and can do so rapidly, bone not obstructing. The removal of a piece of cranium and replacement of the skin-flap is accompanied by so little danger that this plan offers advantages, especially so when the prolonged bone-cutting, which is necessitated by an intact cranium, is to be followed by a long piece of intracranial surgery.

It is worth while remembering that, opening the skull, even in incurable cases, may diminish pain and optic neuritis. The dura is to be divided and turned aside as a flap, the line of division being about one-third of an inch internal to the bone section, so as to permit of suturing and replacement. Generally speaking, the dura is to be respected and treated as are other serous membranes, and with no more consideration.

From the skin hemostatic forceps have sufficed to arrest hemorrhage. With a transverse bar at the top, a T-shaped blade, a large area of skin would be pressed upon and so bleeding be better arrested; perhaps the T-shaped blade could be covered by rubber with advantage. By encircling the cranium with a rubber band he has not had satisfactory results. Hemorrhage from the bone during the cutting may be arrested by Horsley's putty, or pressure with dry gauze. By crushing in the edges of the bone with heavy forceps bleeding from the diploe has always been arrested. From the dura, a fine thread passed around the artery and tied has sufficed to stop bleeding. From veins the same may be said. Where hemorrhage comes from a sinus, he has arrested bleeding in several ways: by suturing the wound in the vessel with a curved needle, passing the thread around it and tying it; by gauze pressure—these methods have been sufficient in his hands. After turning the dura back and ex-

posing the surface of the brain vessels are to be sought for and tied carefully, without dragging, by two threads, and divide between. Forceps will generally tear off, and should not be employed, save very temporarily. It might be that serrefines would be of use.

It is worth while to call attention to the fact that tumors within the brain will push up sulci from below so that vessels can be tied more easily than in the normal brain. A growth should be encircled by ligatures under these circumstances. The material used in ligating will be at the surgeon's pleasure. The author uses very fine sterile silk. Finally, there is that form of hemorrhage which may come from the exposed surface after removal of a growth, and is usually denominated parenchymatous. There is nothing so effectual in arresting this as pressure with gauze. It may be that the gauze can be taken away at the end of the operation; usually, however, it is to be left protruding and removed in two or three days. In a recent case under the author's care the gush of blood after the removal of the tumor was enormous, yet ceased promptly on packing.

In regard to the anesthetic: special indications for one or the other anesthetic lacking, the writer employs chloroform, intracranial congestion being probably lessened thereby. It is a well known fact that under ether the face becomes congested; it is reasonable to presume that a similar condition may obtain within the skull.

Tiffany has a cast of the brain at hand to refer to while performing operations on the cranium, in order to compare it with the exposed area. Electrical stimulation of the exposed area by the methods at present in vogue gives most efficient aid to the operator.

When operating for a tumor of the brain, which is covered by the cortex, the color and consistency of the exposed area may give information, but an incision will probably be of advantage. Certain growths have the same consistency as the brain, and have been traversed by needles without recognition, hence color and consistency failing to be recognized, probably an incision into the brain is best; touch followed by incision, if the tumor does not present, is a far better way than touch followed by puncture, unless a cyst is recognized as present.

Of the tumor it is scarcely necessary to speak, but the removal of the cortex is a matter about which much can be said. Undoubtedly

in many cases of tumor, the cortex is greatly displaced, but it is also probable that where the cortex is removed restoration of function, to a certain extent at all events, will follow. Circumscribed growths may be taken away by spoon, finger, knife, etc., but infiltrated growths, while they may be taken away, so far as can be recognized by the operator, give most unsatisfactory ultimate results, recurrence being the rule. The dura, being removed, should be replaced by gold foil, to prevent adhesions between brain and scalp.

Intracranial sutures of silk are advantageous. To obtain a bone flap where it is thought necessary, when the natural bone is wanting, different expédients have been made use of: thus the periosteum from the tibia has been transferred to the head; the outer table of skull, while connected with the skin, has been fashioned as a flap to turn over and cover the defect; the removed bone, perforated with holes so as to permit of drainage, has been used, etc. For the skin he always uses subcutaneous sutures of silkworm-gut. A voluminous dressing of sterile absorbent gauze has done all that is necessary. He has not closed completely a head opened for an extensive operation, save in one or two instances, and here he has had occasion to regret his method. He drains by means of a piece of silver wire hooked in the lower angle of the wound, and believes that his patient's condition will be improved thereby. The time when dressings are to be changed will vary with the condition of affairs present; and it is scarcely necessary to call attention to the fact such re-dressing is to be carried out with the precautions for cleanliness which characterized the first dressing.

#### *JONNESCO'S METHOD OF NEPHROPEXY.*

This is described and illustrated in the author's new journal, the *Revista de Chirurgie* (No. 4), published at Bucharest. After an incision parallel to the twelfth rib, or if too short the eleventh, the kidney is brought up to the wound. The adipose capsule is detached and turned back from the entire outer side of the kidney, which is then fastened to the rib by three double silk threads, or better still by two U-shaped pieces of silver wire, each end inserted separately with an Emmett needle passing through the skin, through the M. sacrolumbaris, the lower aponeurosis, and through the fibrous capsule on the rear side of the kidney, through the renal parenchyma 1.5 centimeters from the

outer side of the organ, then through the fibrous capsule on the other surface, through the periosteum of the twelfth rib, and finally out again through all the layers, three centimeters beyond the wound. The ends of the threads are tied over a long roll of sterile gauze on each side of the wound, and the organ is thus fastened to the rib at each end and in the middle, with the ureter in its normal position. He has performed this operation ten times on patients and many times experimentally. He is careful to keep his patient in bed twenty days, and removes all the threads or wires the tenth day, thus obviating all the inconveniences of permanent threads. The adhesions between the decorticated parenchymatous surface, the rib and the muscular tissues, form a remarkably firm support, and "all the disadvantages of other methods are absent."—*Journal of the American Medical Association*, Sept. 18, 1897.

#### DISEASES OF THE GLOSSO-EPIGLOTTIC SPACES.

J. F. BARNHILL (*The Laryngoscope*, vol. iii, No. 2, 1897) presents an article on this subject because: First, the subject being comparatively new, little is said concerning it in text-books; and medical journals have had fewer articles concerning this locality than about others of less importance. Second, the rather large number of cases he has seen who have received treatment for catarrhal conditions at the hands of specialists of experience, the patients having been skilfully treated in a limited way, every pathological condition having received careful attention, from the *alæ nasi* to the cricoid cartilage, excepting the spaces between the tongue and epiglottis; and yet these patients considered themselves uncured, complaining of many or all of the symptoms enumerated in the body of the author's paper. Third, the frequency of the diseases of the spaces, and the importance of recognizing and appropriately treating the same.

The pathological conditions found in these fossæ are, giving them somewhat in the order of their frequency, hypertrophied lingual tonsil, varicose veins, papilloma, fibro-sarcoma, and carcinoma. Syphilitic and tubercular ulcerations are found here. The spaces, particularly when occupied by a growth of any kind, are quite subject to acute and chronic inflammatory conditions.

As to symptoms, a considerable number of patients under the writer's care for other ail-

ments have been observed to have greatly enlarged lingual tonsils without any complaint whatever, and it has not been uncommon to find hypertrophies in these spaces large enough to infringe upon or even overhang the epiglottis, with the patient disclaiming all knowledge of anything ever having been wrong with the throat. Others with much smaller and comparatively insignificant growths complained of many or all the symptoms here enumerated. He accounts for this in two ways: first, in persons of highly sensitive nervous systems, the slightest touch of a foreign body against the hypersensitive epiglottis will excite the reflex centers of the air tract in a degree that would not be possible in one whose nervous tone is normal; second, the conformation of the epiglottis in many cases is such that instead of standing up and away from the base of the tongue, as it normally should, it curls unduly forward, projecting its crest directly against the base of the tongue and over the glosso-epiglottic spaces, thus unduly infringing upon the smallest nodule of lymphoid tissue, and giving rise to symptoms equal in severity to those found in cases where the spaces are filled with tumors many times larger, but with normal epiglottis.

A feeling of irritation, fulness, and a disposition to clear something from the throat is a very constant symptom. Cough, varying in degree from an occasional dry hack to the most distressing and frequent paroxysms, is common. Such violent coughing sometimes ruptures one or more of the venous radicles of the spaces, which are often varicose, and particularly in patients past middle life, thus giving rise to a smart hemorrhage, which as a matter of course greatly alarms the patient and may prove perplexing to the attending physician, if he be not skilled in the use of the laryngoscope.

Many cases cough but little, and feel but slight annoyance, except at the time of taking food, when there are violent paroxysms of coughing, sometimes producing vomiting. Functional heart disease is often much aggravated and sometimes wholly caused by disease of these spaces. Hysteria usually accompanies these cases.

Many cases are nervous or anemic, and a considerable percentage of the female patients have menstrual disorders. The peculiar nervous state at the menopause, together with the increased tendency toward varicose veins, causes suffering at this period from conditions that had before gone unnoticed.

Such cases require constitutional treatment appropriate to each.

Tumors of the spaces, which have been so innocent as to be unnoticed by the patient, should be let alone. Where annoying symptoms are present, extirpation of any hypertrophy should usually be advised. Surgeons differ as to methods of removal, some preferring excision, some the wire loop or galvano-cautery, while a few believe caustics and iodine compounds quite sufficient. The author always uses the snare when the growth projects sufficiently to be readily engaged by the wire loop. When the tumors are flat or small he employs Myles' lingual tonsillotome. Patients complain much less of pain, and there is very much less inflammatory reaction and general distress when the snare or tonsillotome has been used. The cure is also more rapid. He uses the electro-cautery on varicose veins, very small hypertrophies that are difficult to engage in the snare or tonsillotome, and for other reasons which rarely arise. The cautery gives rise to but very little pain at the time, the part being thoroughly cocainized, but the after-pain and distress usually arising from the inflammatory reaction set up in the loose tissue of the spaces has been in the author's hands the source of such great annoyance that he now resorts to this method only in selected cases.

When electricity has for any reason been used, he has observed the least trouble and the best results when he employed a blade or needle-pointed electrode which could be plunged into the center of the growth and the destruction thus be accomplished from the center outward. As a matter of course, great care should be exercised not to use the cautery too freely, one or two nodules only being punctured at a sitting, and the greatest care exercised in avoiding injury to neighboring healthy tissues.

The author has never used chromic or other acids as destructive agents in this region, knowing the difficulty with which the space is rendered sufficiently dry to prevent spreading of such agents to surrounding tissues. With one exception he has abandoned the use of the various iodine compounds and other so-called sorbafacients, their action, if at all beneficial, being so slow that patients either cease their visits or ask to be relieved by the more rapid method of extirpation or destruction. The exception referred to is the iodine and carbolic acid compound recommended by Chappell. This preparation has

the decided merit of sticking to the spot to which it is applied and not spreading to adjoining healthy tissues. Its application is about as painful as the more radical methods, and requires so much longer time to accomplish its purpose that one is only justified in using it with timid patients who are afraid of all "operations."

---

#### THE OPERATIVE TREATMENT OF OCCLUSION OF THE JAWS.

J. EWING MEARS (*Journal of the American Medical Association*, Sept. 18, 1897) in a paper on this topic states that the affection occurs in two forms—the spasmodic or temporary, and the chronic or permanent. The former usually occurs in connection with some condition which affects the motor filaments of the third division of the fifth nerve, causing spasmodic contraction of the elevator muscles of the lower jaw. Among the causes may be enumerated the delayed or difficult eruption of the third molar or wisdom tooth of the lower jaw, the development of tumors from the external surface of the ramus and body of the lower jaw, alveolar abscess in connection with the posterior teeth, necrosis of the jaws, suppurative tonsillitis; and it may follow operations on the lower jaw when performed in the molar region. It may be proper to include tetanus under the temporary form of jaw-closure. This form differs from those described above by reason of the fact that the jaw-closure is one among other symptoms which are present.

The treatment of the temporary form of jaw-closure consists in the removal of the causes. When dependent upon the impeded eruption of the wisdom tooth, the mouth should be opened by levers, the patient being placed under the influence of an anesthetic, and the second molar tooth should be extracted so as to afford space for the third molar, or as the latter is not infrequently found to be an imperfectly developed tooth, the offending organ should be removed. Where tumors, necrosis and alveolar abscesses exist as causes, the treatment is obvious. For the relief of trismus, which is so prominent a symptom of tetanus, remedies which are efficient in controlling the general condition will afford relief.

Under the improved methods of treatment the prognosis of jaw-closure may be regarded as favorable. Even in the most inveterate cases, in which the entire buccal spaces on both sides have been obliterated by masses of

nodular tissue, operative treatment promises relief.

Having failed by the employment of the different methods in vogue, the author was led, in a study of the character of the pathologic structure which existed and of its marked tendencies to union after section as well as its reproductive power, to the adoption of a method by which normal mucous membrane should form behind the cicatricial mass. It was evident that if such a line could be formed the pathologic tissue in front could be severed without fear of union occurring, and the divided portions could be kept separated and their nutrition modified. In performing the operation a long-handled, slightly curved needle armed with a strong aseptic twisted-silk ligature of sufficient length is introduced at the angle of the mouth on the inner surface and carried carefully into the space between the cicatricial mass and the buccinator muscle, and the point made to emerge at the position of the last molar tooth of the lower jaw—at which point the posterior border of the cicatricial tissue can usually be felt. The ligature is now seized with the toothed forceps, the needle withdrawn, and the ends tied, the ligature lying loosely in the channel thus formed. As the intention is not to divide the mass by the ligature it is permitted to remain without traction, the formation of the canal lined by normal mucous membrane being facilitated by drawing the ligature backward and forward, and thus destroying any adhesions which may form. The introduction of a probe curved so as to easily take the direction of the canal is also of service, and gives the surgeon information as to its condition. When the probe passes readily and smoothly and without provoking bleeding, it may be assumed that the canal is lined by normal mucous membrane. When this condition is established beyond a doubt, usually at the end of three weeks, a grooved director curved in a proper manner is introduced into the canal and a blunt-pointed bistoury is carried along the groove, dividing the tissue as it advances. This being accomplished a gag is placed between the teeth and the mouth forced open to its widest extent. The buccal space is then packed with five-per-cent. iodoform gauze, which is replaced the third day, the cavity being thoroughly cleansed with a disinfecting solution at each dressing. At the expiration of the second or third day the gag should be used, opening the mouth to its widest extent, and each day this should be

practised until there is evidence of the formation of normal membrane lining the buccal spaces, and the patient can without the aid of the gag open the mouth freely; the iodoform packing may be diminished as the reparative process advances. In some instances the author has provided patients with a gag and advised its use from time to time, in order that the newly formed membrane may be kept pliable. In a few months—three to four—its use may be dispensed with. This method overcomes all the objections to the plan which involves the creation of a false joint in front of the cicatrix, and secures as perfect a result as possible.

In conclusion Mears states that jaw-closure due to the presence of cicatricial tissue in the buccal spaces can be most efficiently relieved by the formation of a canal lined by normal membrane, by means of a ligature passed behind the cicatricial mass; reunion of the divided tissue and reformation of the nodular tissue not occurring after division when this canal has been formed.

Synostosis of the temporomaxillary articulation, producing jaw-closure, can be best relieved by removal of both coronoid and condyloid processes with the upper portion of the ramus, thus affording ample space for the formation of a freely movable false joint. The operation should be performed through the mouth, thus avoiding disfiguring cicatrices.

---

#### MIXED TUMORS OF THE SOFT PALATE.

BERGER (*Revue de Chirurgie*, No. 7, 1897) concludes a paper on this subject with the following propositions:

The mixed tumors of the soft palate present a distinct group showing well marked anatomical and clinical characteristics.

These tumors originate in the glandular layer of the palate and are always encapsulated. They are epitheliomatous in nature, with a varying framework.

In some cases the epithelial elements are deposited in the manner characteristic of adenomata; in others of that noted in epitheliomata included in a fibrous, mucous, or cartilaginous framework. These growths are essentially benign; neither in course nor in termination do they resemble true epitheliomata. This benignity is attributable to the distinct limitation of the epithelial hyperplasia by the mucous or cartilaginous capsule. None the less these tumors can be distinguished from sarcoma only with diffi-

culty, since the latter growth in the region of the soft palate may be slow in its progress, distinctly encapsulated, and relatively benign.

The sole danger connected with these tumors is their increase in size and consequent interference in function. Their extension toward the pharynx, the pterygo-maxillary region and the parotid render their extirpation somewhat difficult. This operation, however, may be accomplished by enucleation because of the distinct capsule. Local recurrence is always due to incomplete ablation.

Tumors of the hard palate are similar to those already mentioned, but they often perforate the bony vault and attack the nasal fossa and the maxilla. They are less clearly defined than tumors of the soft palate and some of them are of the same nature, having been derived from the palatine glands; others may be more properly classed as sarcomata, particularly the plexiform sarcoma and the angio-sarcoma.

#### THE SUCCESS OF SALOL IN GENERALIZED SCLERODERMA.

A. PHILIPPSON in the *Deutsche Medicinische Wochenschrift* of August 12, 1897, reports two cases treated with salol. The improvement in both was marked and permanent from the start. The pruritus ceased at once, and the skin regained its suppleness and the members their flexibility in eighteen months in the first, a very severe case, and a little later in the other, a woman of sixty-nine. The dose in the first case (a young man) was forty-five to sixty grains a day, in the other twenty to thirty grains. No inconveniences were observed from its prolonged use. Massage and gymnastics were ordered as indicated.—*Journal of the American Medical Association*, Sept. 18, 1897.

#### SARCOMA OF THE TONGUE.

MARION (*Revue de Chirurgie*, No. 7, 1897) in the course of a paper upon Sarcoma of the Tongue, being a report of cases, advises early extirpation not only of the tumor, but also of a considerable portion of the apparently healthy tissue surrounding it. This is facilitated by splitting the cheek. The resulting scar is scarcely perceptible. This first intervention is sometimes efficient, as in the cases of Butlin and Mercier, Poncet, and others. If following this first ablation sarcoma becomes generalized in the cervical ganglia or elsewhere, radical surgical treatment must be abandoned; the surgeon's efforts must be

confined to avoiding the accidents of generalization, such as asphyxia by compression. If there is local recurrence the tumor should be again removed, Marion arguing against total ablation of the tongue. Following this procedure he quotes several successful cases. As to enlargement of the ganglia, the majority of cases are inflammatory; none the less they may be sarcomatous, hence all enlarged glands should be removed, though the outlook in such conditions is extremely unfavorable. In unfavorable cases the author suggests antisarcomatous injections. He quotes one case in which injections of pyoktanin were followed by subcutaneous enucleation of the growth and cure. At first every second day, then every six days, thirty minims of 1:1500 solution was injected into the base of the tumor.

#### RESECTION OF HALF A CANCEROUS STOMACH.

DERIAJINSKY (*Revue de Chirurgie*, No. 7, 1897; quoted from *Annales de la Société de Chirurgie de Moscou*, t. xv, No. 4) operated upon a woman, forty-six years old, who had been vomiting for nine months. She was in good condition and a large tumor was distinctly felt. On opening the peritoneum a neoplasm was found occupying all the pylorus, nearly the entire lesser curvature of the stomach, and a portion of its posterior wall. In spite of its size the growth was extremely movable, and the author, deciding to remove it, completely dissected all that portion of the stomach in which it was placed—that is, the entire pylorus and the lesser curvature to the cardiac orifice. There remained only the lower half of the stomach, which was closed by suture and secured to the divided duodenum. The operation lasted three hours. The author stated later that the patient suffered from parotiditis and obstinate diarrhea. The wound suppurated. None the less the patient began to recover, but on getting out of bed five weeks after operation was taken with green vomiting, which lasted for five or six days, when she died with phenomena of cardiac paralysis. Autopsy showed death was due to septicemia, but the results of operation were satisfactory, the suture having held completely.

Although this case ended fatally it is interesting as showing that with better technique such extensive resection of the stomach may be a feasible operation.

*THE TREATMENT OF GOITRE.*

SERAFINE (quoted by *Revue de Thérapeutique*, July 15, 1897) states that treatment of goitre by thyroid gland is best adapted for the form known as struma parenchymatosa. Definite cure is rarely observed and only in young subjects. The results are satisfactory in sixty-three per cent. of cases, the goitre lessening in size. In thirty per cent. of the cases the treatment is absolutely valueless. When goitre has undergone secondary degenerations, such as colloid or cyst formation, the treatment is useless. The effect of treatment is manifested almost immediately, and the dry thyroidin is more potent than other forms of the gland. Thyroidin is not indicated in Basedow's disease, excepting at the very beginning of the affection when the symptoms are pronounced; not only is the treatment useless, but even dangerous. The therapeutic effects are transitory, hence the thyroid extract should be given from time to time.

*THE RADICAL CURE OF HERNIA.*

LANNELONGUE (*Revue de Thérapeutique*, July 15, 1897) reports in all thirteen cases, the youngest four months old, the oldest sixty years. The technique consisted in injections about the hernial sac, guided thereto by the bony fibrous tissues surrounding it. The patients are subject to no previous preparation. The author does not object to the administration of a purgative the night before.

He advises that in adults the condition of the kidneys should be examined into and states that with this end in view he employs the procedure of Achard because of its simplicity. This is as follows: One cubic centimeter of a five-per-cent. solution of methylene blue in distilled water is injected into the buttock after the patient has emptied his bladder. Half an hour, one hour, an hour and a half, and every half hour until six hours have passed the patient is directed to urinate, each time in a separate glass. If the kidneys are healthy the dye should be passed in the course of the first hour; if it is not passed for two hours there is a diminution in the eliminative power of the kidney; and great retardation indicates advanced disease. If the urine passed in the first two hours is not tinted it should be shaken up with chloroform; if the latter is colored the blue has passed.

As to technique of the hernia treatment the greatest care should be taken not to inject the fluid into the peritoneal cavity and not to

wound the cord. The first accident is avoided by reducing the hernia and by keeping it reduced by the fingers of an assistant carried into the internal ring. Chloroform should be given to complete relaxation. After the field has been prepared antiseptically two series of injections are made: the first internal to the cord, which is protected by the index finger of the left hand; the second, external and somewhat behind it. Each series is made up of three injections of ten minims of ten-per-cent. solution of chloride of zinc. As the injections are completed the fingers of the assistant, which are employed to hold up the hernia, are replaced by a tampon of gauze and cotton reinforced by a large amount of absorbent cotton and held in place by a spica of the groin. The latter is removed the third or fourth day, the suspensory being employed in cases of scrotal edema.

---

*A CASE OF STREPTOCOCCIC SEPTICEMIA  
TREATED BY ANTISTREPTO-  
COCCIC SERUM.*

Wratsch, No. 21, 1897, reports the case of a man twenty-three years old, suffering from streptococcic septicemia. Diagnosis was made by blood examinations which gave pure cultures of this microbe. The patient was extremely ill with all the typical symptoms of the aggravated form. There was marked improvement following the third injection, which was progressive and finally ended in cure. Convalescence was retarded by gangrene, which required amputation of both feet.

*CYSTITIS IN NURSING CHILDREN.*

FINKELSTEIN (*Revue Pratique d'Obstétrique et de Gynécologie*, July, 1897) calls attention to the frequency of cystitis in the course of infectious diseases attacking nursing children. He has observed over thirty cases, all under one year of age and nearly all girls, suffering from bronchopneumonia, acute gastro-enteritis, meningitis, etc., which nearly always ended fatally. The etiology of this affection, the author believes, is nearly always dependent upon retention, the result of the grave general disease. This retention of course renders the bladder vulnerable, bacteria penetrating by way of the blood or from the rectum or along the urethra.

As a result of autopsy the author believes the urethral route is the ordinary one, since in the cases he observed the urethra was nearly always soiled with fecal matter. The

absence of colon bacilli in the blood and the other organs would seem to exclude the hematogenic infection.

This communication is important since it calls attention to the necessity of examination of the bladders of extremely ill children and the use of a catheter when retention is observed; also, it impresses upon the nurse the importance of frequently changing diapers and of carefully washing the vulva and the urethral outlet, especially in cases of gastro-enteritis.

#### *TREATMENT OF EXOPHTHALMIC GOITRE.*

At a recent meeting of the Academy of Medicine of Paris (*Progrès Médical*, July 31, 1897), a paper by Jaboulay was read dealing with nine cases of section of the cervical sympathetic for exophthalmic goitre. The results were good, both with respect to the exophthalmus and to the goitre and palpitations. The best effect was obtained in young people in whom presumably the accelerator system of the heart was less developed and more thoroughly modified by the division of the sympathetic. In cases of failure of the treatment an explanation might be found in the existence of two sympathetic cords in the neck—a not infrequent anomaly. At the same meeting Doyen reported two cases of exophthalmic goitre successfully treated by thyroidectomy. He preferred this operation to division of the cervical sympathetic, both on account of its safety and for its beneficial results. Such cases seemed to demonstrate the pathogenic rôle played by hypersecretion from the thyroid.—*British Medical Journal*, Aug. 28, 1897.

#### *SUPPURATING CHONDRO-OSTEOSARCOMA OF BREAST.*

ST. ARNOLD, of Lucerne (*Virchow's Archiv*, vol. cxlviii, part 3, June, 1897), describes an interesting case of this rare disease in a lady aged sixty-seven. She had noticed, in the spring of 1895, a swelling in the left breast, but her family doctor believed that it had already existed there for some time. Diagnosis at first was doubtful. The swelling grew steadily and became painful. After traveling the patient consulted a doctor at Zurich, and he diagnosed mammary abscess. As pus escaped when he made an incision he naturally believed that his original opinion was correct. The swelling, however, increased, and fever set in, with extension of

inflammation to the circumference of the breast. The patient became exhausted and slightly delirious. Lünig found the breast much swollen and surrounded with dilated veins and lymphatics. In the midst of the swelling was a cavity, which was packed with iodoform gauze. Its walls were very firm, and it discharged fetid pus. The axillary glands were not enlarged. Lysol was freely applied, but the temperature rose over 105°, and the patient seemed too weak for an operation. At the end of a week after she had been under Lünig's care she seemed worse, and nothing appeared of any avail except to remove the focus of suppuration. The breast was therefore amputated and the wound thoroughly drained. Two days later the fever had disappeared. Two months after the operation the patient was in excellent health, and there was no sign of recurrence. The tumor was very tough and full of small tuberosous masses. On examination St. Arnold found that it was a sarcoma containing bone and cartilage.—*British Medical Journal*, Aug. 28, 1897.

#### *A STUDY IN EPILEPSY.*

WHARTON SINKLER and F. SAVARY PEARCE present a careful consideration of the subject of epilepsy in the *Pennsylvania Medical Journal* for September, 1897. As to treatment the authors point out that the condition must be battled with along the lines of heredity. The history of this disorder being in a family should interdict marriage; the history of insanity should do likewise. This hope may be only partially realized. Hygienic care of the patient should be enjoined. Attention to reflex disturbances in any of the special senses should be well worked out and corrected. Especially should diet and idiosyncrasies of the patient as to food be guarded. Indigestion is, no doubt, an exciting cause of epilepsy and of attacks. Gastro-intestinal therapeutics is of great value. Lavage has an important place in the therapeutics of epilepsy, as pointed out by Herter and Rachford. Intestinal antiseptics, as potassium permanganate and salol, do especial good in those cases which have fermentative dyspepsias.

Bromides are the standard remedy to stay the spells, and should be given sparingly. Many cases have the disease "bromism" engrafted upon the epilepsy by want of care of the physician.

Digestants will often aid in lessening attacks as much as any cerebral depressant.

Indeed, strychnine may be indicated where atony of the general system obtains.

Other drugs that have been of service as substitutes for the bromide treatment are trional, *Solanum Carolinense*, etc., and finally Flechsig's opium treatment may do good in exceptional instances.

Hypnotism deserves mention as a possible means of relief of epilepsy, but has not as yet been used enough to more than be a trial. Like all new impressions upon an individual case it may do good, temporarily at least.

In view of the recently advanced theory of motility of the neuron, and assuming this to be the cause of essential epileptic convulsions, hypnotism is worth a wide investigation.

Specific treatment should be judiciously employed where syphilitic origin is suspected; but this should not be persisted in to disorder the gastro-intestinal tract and other functions.

Trephining will be indicated in fracture and superficial neoplasms. Post-epileptic manias should be watched for as a guard against homicide. Commitment to an asylum may be a *dernier ressort*.

After all our care in treating this disease, it will be found that to our surprise a small percentage are cured, and a very large amount of amelioration of the severity and frequency of attacks is accomplished.

#### INCISION OF THE KIDNEY IN UNCOMPLICATED NEPHROLITHIASIS.

C. G. CUMSTON in the *Annals of Surgery* for September, 1897, advocates the following treatment: Operative measures being decided on, the patient is placed, as in any operation on the kidney, in the lateral decubitus, on the side of the healthy kidney. The loin next the operating table should be well raised up by a large and firm cushion, in order to put on the stretch the parts to be operated on. The thigh on the side of operation should be slightly flexed.

The operator stands facing the patient's back and an assistant on the other side of the table opposite him. The twelfth rib, the crest of the ilium, and the external border of the sacro-lumbar muscular mass are located by palpation. The proper incision to select in order to reach the kidney with ease has been a matter of much debate among surgeons. All the various cutaneous incisions have been pretty thoroughly tried: the vertical incision

of Simon, with a prolongation over the ribs and buttock; Czerny's incision extending outward from the last rib; Guyon's oblique incision; Morris's very oblique incision, and that of Le Dentu, which is parallel to the twelfth rib. Tuffier's incision begins at the eleventh rib, about eight centimeters from the spinous apophysis, and is carried down to the iliac crest. If the kidney is in its normal position, this incision should be parallel, or nearly so, to the twelfth rib, but if the organ is found by palpation to be lower down than normal, the incision should be made slightly oblique downward and outward.

If Tuffier's incision be chosen—and it appears to the writer the best of those already proposed—the skin being incised, we fall upon the subcutaneous cellular tissue, which in stout subjects is quite thick. This is in turn incised, and the lower fibers of the great dorsal muscle will be seen in the upper part of the incision. The great dorsal muscle is incised, and then the great oblique; then underneath these we come to the small oblique and the white, glistening aponeurosis, which is the point of insertion of the transverse muscle. A few small vessels coming from the posterior lumbar vessels will be cut during the incision, but the bleeding is easily controlled by artery-clips.

The wound is then wiped out with gauze tampons, and then the upper part of the border of the quadratus lumborum may be seen. It is not necessary to incise this muscle. Then below a large nerve trunk, which is the first lumbar pair, will be seen following nearly the same oblique direction as the incision. Only one more layer of tissue now remains to be incised; it is an offshoot, so to speak, of the aponeurosis of the transverse muscle, and passes in front of the quadratus lumborum. This aponeurosis is very thin, so much so that in most subjects the subperitoneal and perirenal fat may be seen by transparency.

The nerves cut in this operation are of no account, as only a few fibers of the perforating lateral branch of the twelfth intercostal nerve are in the way.

There is, however, one accident that must be avoided in incising the lumbar walls, and that is opening the pleural cavity, which at the costo-lumbar hiatus of the diaphragm is only separated from the renal fat by a very thin layer, coming down from the concave aspect of the diaphragm to the quadratus lumborum. For prudence' sake it may be advisable to open the aponeurosis of the

transverse from below upward, then introducing the finger into the incision in the aponeurosis, the fat and pleural cul-de-sac are pushed upward on the end of the finger.

Next to be accomplished is to get through the perirenal fat, and this should be begun at the anterior aspect of the kidney, as it will be done more quickly by so doing. When the organ has been laid bare it is brought up into the incision, but this must be done slowly so as not to exercise too sudden a traction on the pedicle. If there is any difficulty in bringing the kidney up into the incision, an assistant places his closed fists under the ribs and pushes the organ up into the wound. When the kidney is brought up under the twelfth rib both its sides and ends must be carefully explored, as well as the pelvis of the organ, in order to detect the presence of a calculus. If digital exploration is without result, which is in most instances the case even when large calculi are present, acupuncture should be resorted to. This is done by means of a long, fine needle introduced methodically into the parenchyma of the kidney, centimeter by centimeter, along the convex border of the organ; then in the sides and at the hilum after the exact position of the renal vessels has been located. If the needle strikes a stone, it will transmit a special sensation to the surgeon's fingers.

If neither palpation nor acupuncture reveal the presence of a calculus, the only alternative that remains is to incise the kidney, and this should be done without the slightest hesitation. Incision of the kidney is perfectly safe, but should be made in such a manner as to involve the least vascularized part of the gland. We may thus attain the calyces and the pelvis of the organ, and the incision is afterwards closed by sutures without the least harm being done to the vitality of the organ. The pelvis of the kidney should never be incised, even if the calculus is felt within it, because the incision is likely to heal imperfectly, resulting in a urinary fistula.

Before incising the kidney, which should be done on its convex border, preventive hemostasis should be secured by compression of the pedicle, either between the fingers of an assistant, if the patient is thin and the opening sufficiently large, or between the operator's fingers of the left hand. Forcipressure can also be used by covering the blades of a clamp with rubber tubing.

Believing, however, that the majority of surgeons would prefer applying a clamp to the pedicle, as in the writer's experiments on

the cadaver it was found that digital compression was very tiresome and not secure, he has devised a clamp for this purpose.

Preventive hemostasis is absolutely necessary, as no hemorrhage can occur, and the field of operation is unobstructed by blood. Compression of the pedicle with clamps does no harm, and may be kept up without danger for half an hour, as is claimed by Tuffier, without any bad result.

In order to reach the pedicle and properly apply the clamp the fingers should be passed down by the easiest opening. By following the concave aspect of the organ the fingers will feel the pulsations of the artery. If a clamp is used, it is simply introduced along the fingers, using them as a director.

The kidney being held in the incision, it is incised on its convex aspect for from four to ten centimeters, and the incision should be carried down deeply in the parenchyma, so as to open into the pelvis of the organ. The slight oozing that takes place is rapidly mastered by packing the incision with gauze for a few moments. The finger is then passed into the kidney, and the presence of a calculus lodged in the parenchyma, calyces, or pelvis is sought for. If nothing can be felt a very fine ureteral bougie should be passed down along the ureter to make sure that the calculus has not become lodged therein.

When the calculus or calculi have been found they must be removed. If the stone is small and movable the finger alone can generally remove it from the kidney. If, on the contrary, it is lodged in the parenchyma, a small forceps or better a curette must be employed. If the calculus sends off prolongations into the calyces, a careful dissection must be made with the knife, as has been done by Tuffier, and the resulting wound closed with fine catgut sutures.

Tuffier was the first to demonstrate experimentally that immediate suture of the renal parenchyma could be done while compression of the pedicle was still applied, with the result that all hemorrhage was prevented after the compression was removed, and that an exact union by first intention took place, and which did not allow the urine to escape from cutaneous fistula in the lumbar incision. Applied to man, this method has given remarkable results.

All that is necessary is a good, curved needle, and stout catgut of large size. The borders of the renal incision are brought together and held in apposition by an assistant while the sutures are being passed deeply

through the parenchyma. Each suture is tied as soon as inserted, from four to eight being sufficient, according to the length of the incision, and should be only moderately tight, because it must be remembered that there still being a compression of the pedicle the kidney is empty of all blood, and consequently it is easy to approximate the borders of the incision. But when the clamp is removed the organ greatly increases in size by the return of the circulation, and the sutures will compress the parenchyma so that the organ becomes lobulated, and if the catgut has been tied too tightly it will cut through the tissues, an event that is to be avoided.

The pedicle clamp should only be removed when the catgut sutures have been tied, and what is most astonishing, not a single drop of blood will be seen to ooze from the renal incision, if the sutures have been properly applied.

After having made sure that hemostasis is complete, the kidney is dropped back into its place, and the perirenal fat is closed over it by a running suture of fine catgut. The external incision is in turn closed, according to the method employed by each operator.

---

**SUBMUCOUS UTERINE FIBROID: OPERATION UNDER GRAVE CONDITIONS; ULTIMATE RECOVERY.**

CH. PLATON (*Marseille-Médical*, March 15, 1897) operated upon a patient who suffered for five years from nearly continuous hemorrhages and all the classic symptoms of a uterine fibroid. She was profoundly anemic, and nearly cachectic. Two tumors were felt in the abdomen: one was median, and as large as a man's head; the other was on the left side, and was much smaller. The patient was not operated upon at once, in the hope that her general state of health would improve; but the hemorrhage continued, and the temperature began to rise, so the abdomen was opened, and the uterus, containing a large submucous fibroid of the fundus, was removed (total abdominal hysterectomy). The smaller tumor felt at the side turned out to be a small ovarian cyst. The patient nearly died on the table, and required hypodermic injections of cognac and of Hayem's artificial serum. These injections had to be repeated several times during the first few days after the operation, and recovery was further delayed by the occurrence of three stitch abscesses in the abdominal wound.—*British Medical Journal*, Aug. 28, 1897.

**THE "R." TUBERCULIN.**

SLAWYK of Heubner's clinic (*Deut. Med. Woch.*, July 22, 1897) reports upon fifty injections of the new tuberculin. One child received twenty-three, another twenty-one, and the two remaining ones two injections. The smallest quantity injected was  $\frac{1}{1000}$  milligramme, and the largest six milligrammes. Full details are given of the first two cases. The elder child, aged  $8\frac{3}{4}$  years, reacted vigorously, whereas the younger and weaker child showed no symptoms. The reaction consisted in fever, sweating, collapse, local redness (and even eventual abscess) of old scars and of the injection site. The patients did not become accustomed to the agent after increasing doses. The highest temperature occurred most often on the day of the injection, but the fever lasted sometimes for several days. The general condition was very little affected by the fever. In one case evening rises of temperature and sweating were noted. A severe collapse once followed an injection, giving rise to grave anxiety. With children great caution in the question of dose is required. Doubling the dose is not to be recommended, and not more than two milligrammes should be given. Once a fistulous opening appeared in a scar in the neck leading down to a tuberculous gland, but the tuberculous tissue was not discharged through it. No certain conclusions can be drawn as to the value of this tuberculin as the time is as yet too short. In the second case an improvement in the condition of the lungs was observed, and in the first case the body weight increased, the glands became smaller, and the very enlarged spleen diminished in size. The injections were discontinued in the other two cases for independent reasons.

Wörner (*ibid.*) has treated eight cases, including four of lupus, one of scrofuloderma with pelvic abscess, and three of early phthisis. In one case of lupus considerable improvement was noted. Two other cases which had been scraped shortly before the tuberculin treatment showed no recurrence. In the case of scrofuloderma rapid cleaning and even healing of long-standing ulcers took place. Little effect was noted in the cases of phthisis. The author is encouraged to a further trial of this remedy in small doses.

Seeligmann (*ibid.*) reports a case of tuberculosis of the skin and generative organs which was improved by the use of tuberculin.—*British Medical Journal*, Aug. 28, 1897.

*A CONTRIBUTION TO THE EXPERIMENTAL SURGERY OF THE URETER.*

J. WESLEY BOVEE (*Annals of Surgery*, September, 1897) makes some interesting observations under the above caption, detailing the results of four experiments on dogs. In his paper he discusses only such injuries of the ureter as require restoration after its complete lateral division. At present opinion is divided as to the relative merits of uniting the two ends of the cut ureter and implanting the kidney portion into the bladder. Both operations have been done successfully, though bladder implantation far exceeds in the number of cases operated on. To the writer there appears a fairly clear field for each operation, yet some of the best men of the country believe one may be substituted for the other or that only the one should ever be done. Nearly all are agreed that either is preferable to nephrectomy, believing conservation of kidney function is far better than its destruction on one side. Some German operators, of course, claim that the kidney must be removed when the ureter is disabled by such an accident as complete division.

One year ago the writer reported a case in his practise in which while removing a tubo-ovarian abscess the ureter was severed, but the life of the patient was saved and the duct restored by obliquely splicing the cut ends. This was the only time this precise manner of repair had ever been employed either in man or the lower animals.

It has been stated by some experimenters in this line of work that, even if union did occur after such anastomoses, constriction was sure to follow, though the few published cases do not lend support to such statements. On this supposition the author determined to make experiments on dogs to corroborate or refute them. The test was not a fair one, as the size of the ureter in the dog does not compare at all favorably with that duct in man. It is much smaller, and therefore more difficulty is experienced in operations on it in dogs. Again, these animals are more difficult to prepare for such surgery and to control after operation. Sepsis is very liable to complicate abdominal surgery in dogs.

His experiments on splicing the ureter were not altogether satisfactory on account of sepsis and shock. The animals he was able to obtain for the work were too small, both for ease in work and in durability against anesthesia and the operation. The third, however, was fairly successful as to subse-

quent constriction, and was satisfactory as to union of the severed duct.

The first two dogs demonstrated the possibility of securing union after oblique section of the ureter, even in a duct about one-fifth the size of that of the human adult, as was the second.

But subsequent constriction, one of the strongest objections offered to this method of conservation of injured ureters, was not disproved on account of the early death of the dogs. To this extent the experiments were failures. Even had these animals lived sufficiently long for such constriction to occur, and it had occurred, we could find in it no decisive proof that such is the result in man.

While the last two experiments do not demonstrate beyond doubt the feasibility of downward displacement of the kidney to allow approximation of distant points of the ureter in man, they furnish us with prospects for a conservative operation and for the removal of one of the indications for nephrectomy. If, too, it is found feasible, the force of the argument in favor of implantation of the ureter into the various portions of the intestinal canal and on to the surface of the body will be very much weakened. If it will prove to be a practical operation, then its employment will be indicated in cases in which the loss of extent of the ureter is too great to be spliced by any of the four methods heretofore employed. If the portion of the duct disabled be the extreme lowest, then the depression of the kidney will be to permit the operation of uretero-cystotomy, as suturing the ureter deep in the pelvis is very difficult, though the ureteral catheter and the position of Trendelenburg render it much easier of execution. This new operation is not designed for competition with uretero-cystotomy, uretero-ureteral anastomosis instead being the successful competitor of that operation in most cases. On the contrary, it may be employed as a preliminary operation to bladder implantation of the ureter. That the kidney in the dog is more movable than that organ in man is of no importance, for we well know that separating that organ in man from its attachments, other than about the renal vessels, is not difficult. And we will find the elasticity of these vessels, together with their attachments to surrounding tissues near their junction with the kidney, will be the controlling element in the mobility of this organ downward. By careful dissection this limitation can be very materially modified to meet the demands of nearly any requirement.

### STERILIZATION OF SURGICAL INSTRUMENTS.

G. DENIGES has combined Marechal's suggestion that instruments can be protected from rust indefinitely by the addition of a small quantity of some alkaline with the use of a powerful antiseptic, and announces that instruments thus treated are absolutely sterilized, while they suffer no injury, even if left for months in the antiseptic solution. His formula is mercuric cyanide two to five grammes in one liter of water, to which is added five grammes sodium borate or carbonate. It is also remarkably effective and harmless for disinfecting the hands. As the efficacy of sodium bicarbonate has been recently proclaimed in the treatment of purulent wounds, he adds that this might be substituted for the borate. The present low price of mercuric cyanide would be still further reduced if there was more demand for it. Its toxicity has been much exaggerated, as one molecule  $Cy, Hg$  only contains 1.5 cyanogen to 4.5 mercury. It is much superior for the purpose to the bichloride, is less caustic, and does not affect the albuminoids, which are coagulated by sublimate. He hopes to see his formula generally adopted in outside antiseptics and hospital practise.—*Journal of the American Medical Association*, Aug. 7, 1897.

### A NEW METHOD OF SUTURING.

In the *Centralblatt für Gynäkologie* of May 15, 1897, ZWEIFEL describes a new method of applying a continuous suture which possesses the very great advantages of simplicity and rapidity of application. It is the stitch used on many "double-thread" sewing machines, and is applied in the following manner:

A straight, blunt-pointed needle and the curved needle in a handle with an eye in its point are both threaded and the threads fastened at one end of the line of suture. The Peaslee needle is then thrust through both edges of the cut, and the straight needle is each time passed through the loop in the eye of the curved one, and so a continuous suture is made, there being on each side of the incision a thread, while the crossings of the thread are all concealed.

In places where the skin is thin this is of advantage, as it causes the fold to rise slightly in the middle; but in thick or fat skins this rise separates the epithelial edges too far, and then an extra precaution is necessary: either a turn of the thread in the straight needle must be made about the other before each

stitch is taken, or a third thread is employed, which must be passed from one side to the other of the cut each time before the suture is passed through the skin. This keeps the edges flat.—*Medical News*, Aug. 7, 1897.

### PREGNANCY AND LABOR AFTER VENTRIFIXATION OF THE UTERUS.

VIGGO ESMANN (*Hospitalstidende*, June 23, 1897) records the case of a woman, thirty-three years of age, who had menstruated regularly since the age of seventeen, and who had become pregnant after the operation of ventrifixation of the uterus and repair of the perineum "*ad modum* Tait." She had twice previously been pregnant—ten and eight years ago respectively—and prolapse of the uterus, necessitating the ventrifixation (in 1891), had come on soon afterwards. During the third pregnancy she developed a marked ventral hernia in the region of the lower part of the laparotomy cicatrix; for this she wore an elastic abdominal belt. In the hernial sac and adherent to it was part of the gravid uterus; there was some ulceration of the sac wall, and slight hemorrhage from the cutaneous veins. She was kept lying in hospital during the last two months of pregnancy. Labor was tedious, the child presented by the feet, and after twenty-four hours the cervix was sufficiently dilated to allow of its extraction. The uterus contracted well, the placenta was spontaneously expelled, and there was no post-partum hemorrhage. The ventral hernia is to be operated upon later.—*British Medical Journal*, July 24, 1897.

## Reviews.

A MANUAL OF LEGAL MEDICINE FOR THE USE OF PRACTITIONERS AND STUDENTS IN MEDICINE AND LAW. By Justin Herold, A.M., M.D. Philadelphia: The J. B. Lippincott Company. 1898.

This volume of nearly 700 pages, including the index, is devoted, as its title indicates, to the subject of medical jurisprudence. Naturally its publication leads one to compare it, first, with Taylor's well known book on this subject, which has within recent years, and indeed in this very year, been revised and brought up to the present standing of this subject, and second, with the more exhaustive two-volume treatises published in a systematic form and edited, on the one hand by Witthaus, and on the other by Hamilton.

The first point that strikes us in reading

the preface, as being of some importance in connection with a medico-legal work, is the final sentence, which reads: "Should any errors of omission or commission be discovered by readers the writer asks their indulgence, as the work has been prepared in the midst of a busy professional career." It seems to us that this is an unnecessary confession of possible inaccuracy, and at least raises a doubt in the reader's mind as to whether some of the medico-legal statements can be relied upon, if the author is willing to admit at the very start that his text has been prepared under such pressure that errors may have crept in or omissions been made.

Some of the authorities which are quoted in the chapters upon Toxicology are scarcely original and perhaps are not as authoritative as they would appear. In these chapters on Toxicology most of the common mineral and vegetable poisons are considered. For some curious reason hydrate of chloral is discussed under the chapter on Anesthetics. We regret that in a number of instances where statements are made as to small or large doses which will produce or have produced certain symptoms of poisoning, the authorities for these statements are not given. Thus in the case of cocaine we are told that half of a grain has proved fatal when taken internally, and  $\frac{1}{30}$  of a grain has caused violent and dangerous symptoms in a girl of twelve years, while still more remarkable is the statement that the application of  $\frac{1}{100}$  of a grain to the eye of a child of fourteen years produced symptoms of poisoning. It would also have been more accurate to state the doses that are capable of producing death from this drug in "forty seconds." If such a case actually occurred the dose must have been a large one and injected directly into a blood-vessel.

Dr. Herold repeats the old and long since proven incorrect assertion that in addition to nicotine tobacco contains nicotianin. No such substance is known to chemists as an ingredient of tobacco, but the statement that tobacco contains it is repeated from one textbook to another until it becomes wearisome. The statement that nicotine is "more rapid in its effects than even prussic acid" is certainly incorrect, for prussic acid is dependent for its action upon its volatility and rapidity of absorption when it is swallowed; whereas nicotine is not absorbed any more rapidly than many other poisons.

It must not be thought, from the criticisms

which we have offered and the minor errors which we have pointed out, that the book is devoid of interest or value. On the contrary the large experience Dr. Herold has had both directly and indirectly in connection with medico-legal subjects renders much of the material which he has brought together in this volume of considerable original interest, and we doubt not that those who are particularly interested in medical jurisprudence will, after an examination of the book, be glad to add it to the other volumes to which they refer. We believe, however, that for the ordinary practitioner and student of medicine the classical book of Taylor will still remain popular.

LECTURES ON THE MALARIAL FEVERS. By William Sydney Thayer, M.D.  
New York: D. Appleton & Co., 1897.

This is quite a good sized octavo volume of over 300 pages, illustrated with the plates, which have become classic during the last eighteen months, of the malarial organism as seen during investigations by Dr. Thayer and his co-laborer, Dr. Hewetson. Additional drawings have also been added which make the original plates more complete. The volume is one which does exactly what its title indicates, namely, it describes the various forms of malarial fever as they are met with in this country and abroad. The author has satisfied himself not alone with clinical and laboratory research, but has brought to the compilation of these so-called "lectures" a very wide study of the bibliography of the subject, so that almost every page gives evidence by one or more foot-notes of his careful laboratory investigations. We think it a mistake that he should have given so valuable a monograph a title which at first glance would lead one to believe that the pages simply recorded remarks made at clinical lectures upon malarial disease. As a matter of fact this volume is a monograph which should be in the hands of every physician who ever sees a case of malarial fever—and who does not?

There are one or two points in the therapy of the disease on which we think Dr. Thayer might have dwelt more thoroughly, but perhaps if he had done so he would have gotten into debatable ground with little satisfaction to himself and his readers. We repeat what we have just said, namely, we urge upon every physician who lives in a malarial district that he be not satisfied until he has made a careful study of Dr. Thayer's work.

**PRACTICAL PATHOLOGY FOR STUDENTS AND PHYSICIANS.** By Aldred Scott Warthin, Ph.D., M.D., Instructor in Pathology, University of Michigan. A manual of laboratory and post mortem technic, designed especially for the use of junior and senior students in pathology at the University of Michigan. Ann Arbor, Michigan: George Wahr, publisher and bookseller. 1897.

This book may be said to stand intermediate between a manual and a so-called compend, and is evidently constructed with the idea of serving the writer's students. As such it, no doubt, fills the author's want; still in it much is written that is not altogether above criticism, but is, as a rule, clear. That the author has not entirely avoided ambiguity will be seen by his reference to the "ligamentum teres," on page 38, which in the application in which he uses it is not to be found in some works on anatomy, and therefore might be misleading to the student. There is also a slight tendency toward the use of terms beyond the grasp of many medical students. A few errors in statement occur; this is unavoidable in any first edition. Thus, on page 45, we are told that pathologic conditions are frequent in the septum ventriculorum. While, for the most part, the formulæ given in the book are sufficiently clear for the student to follow, occasional exceptions occur. On page 16, of Part II, when describing the method of freezing tissue for sectioning, we are directed to place the tissue "in a drop of solution of liquid gum and syrup." This is not very explicit. Such errors are, however, extremely rare.

The first part consists of 103 pages, and has to do with post-mortem work, and the examination of pathological specimens in general. On page 97 of this part we find directions for curetting the uterus, something not usually considered in place in works on pathology.

The general directions, however, for obtaining material for microscopic examinations are good.

The second part consists of 134 pages, including the index, and has to do with the technique of microscopic examinations. It is, as a rule, clear; an exception, however, may be noted on page 119, in the following statement concerning the examination of the eye: "The fresh cornea is put into freshly prepared 8 filtered lemon juice for five minutes."

Another criticism of the book which may be offered is that it is all bound in one volume, composed of two parts, paged separately, and only the second part indexed. The order given for the post-mortem examination is not that usually adopted.

The book is printed on fairly good paper, in clear type, heavily leaded, and with such a large amount of blank space that one cannot avoid thinking that, to use the language of a printer, it is "padded."

**PRACTICAL DIAGNOSIS: THE USE OF SYMPTOMS IN THE DIAGNOSIS OF DISEASE.** Second Edition, revised and enlarged. By Hobart Amory Hare, M.D., B.Sc. Illustrated with Engravings and Colored Plates. Price, \$4.75.

Philadelphia and New York: Lea Brothers & Company, 1897.

It is stated in the preface that the first edition of this book (a review of which was published in the *THERAPEUTIC GAZETTE* during the fall of 1896) is designed to lead the physician and the student to a diagnosis from the symptoms which he finds present in his patient. In other words, its method consists in taking up the subject of vomiting, for example, discussing its various causes and diagnostic significance and the differentiation of its forms. In the event of a patient suffering from paraplegia it will be found in the chapter on Feet and Legs that the various causes of paraplegia are discussed and the symptoms described in the manner in which they are apt to be manifested by the patient. The book is therefore an endeavor to teach diagnosis exactly as the physician meets it at the bedside, and does not follow the methods usually adopted in works on diagnosis or on the practise of medicine.

The preface is self-explanatory:

"The first edition of this book, which was published in August, 1896, was so rapidly exhausted that the author has had an early opportunity to prepare a second edition, from which the unavoidable faults of a first edition have been expunged and to which many new facts have been added. The author desires to reiterate the fact that the book was written with the hope that it would prove useful as a guide in bedside practise. That the profession needed a book dealing with diagnosis from the standpoint of the symptoms manifested by the patient seems to be evidenced by the rapid sale of the first edition."

**INCOMPATIBILITIES IN PRESCRIPTIONS.** For Students in Pharmacy and Medicine and Practising Pharmacists and Physicians. By Edsel A. Ruddiman, Ph.M., M.D.

New York: John Wiley & Sons, 1897.

This is a useful book, particularly to the young physician, and is designed to guide him in his prescription writing in such a way that he will not make pharmaceutical or chemical incompatibilities. The first part of the book is chiefly interesting to physicians.

In this part the substances treated are arranged in the alphabetical order of their Latin names, except in the case of some of the newer remedies. Under each name is given nearly all the known incompatibilities. Thus, under "*Acetanilidum*" we find nearly half a page in which are detailed the common incompatibilities, and after each statement of incompatibility a brief reference to the authority is given. This part of the book consumes 101 pages. The remaining 130 and odd pages are devoted to prescriptions, with criticisms; a large number of prescriptions containing ingredients which are incompatible are given, no less than 325 being included in this list. Following this under each number is given a rational criticism or explanation of the incompatibility. It is this part of the book which will appeal particularly to the pharmacist. At the close of the book is a table showing the effect of rubbing together equal weights of two solids.

We must congratulate Dr. Ruddiman upon having prepared a very useful manual which will undoubtedly prove most valuable to the two classes for which he has written it, and many physicians, both young and old, will do well to have this book at hand.

**ESSENTIALS OF OBSTETRICS.** By Charles Jewitt, A.M., M.D., Sc.D. Assisted by H. F. Jewitt, M.D. Illustrated.

Philadelphia and New York: Lea Bros. & Co., 1897.

The first sentence in the preface of this small octavo volume of 358 pages states that its object is to place the essentials of obstetrics within easy grasp of the student, and we learn from statements further on in the preface that the authors evidently do not intend that it shall be used for the purpose of supplanting the more exhaustive works which are commonly employed as text-books. As is the custom with text-books on obstetrics at the present time, this one is profusely illustrated with photo-engravings and ordinary illustrations, both of apparatus, of methods of measuring the pelvis, and of the means by which palpation of the abdominal area is usually practised. In a number of instances colored plates have been inserted as for the purpose of showing the fetal circulation or the arrangement of the placenta.

In the presence of the excellent manuals of Reynolds, Davis, Dorland, and others, we cannot state that this is a book which is to be preferred to any other work which can be purchased with the object of obtaining concise obstetrical information; but from a careful examination of the text we feel that we

can truthfully say that there is little choice between this and the standard condensed works of which we have spoken. There is no doubt that the arrangement of the subject and the way in which it is discussed is such as to render the difficult subjects of Embryology and the Mechanism of Labor plain to any student who at the same time will study the larger works which every student of obstetrics should possess. In other words, students of obstetrics can with profit use this handbook as a stepping-stone when seeking for a larger amount of information from more advanced manuals.

**TEXT-BOOK OF THE PRACTICE OF MEDICINE.** By James M. Anders, M.D., Ph.D., LL.D. Illustrated. Philadelphia: W. B. Saunders, 1898.

Although the date on the title-page of this book is somewhat ahead of the times, it being sent out for review during the early part of October, we welcome it as a forerunner of some of the other good books which 1898 will probably produce. In his preface the author ignores the fact that within the last few years the medical profession has been fairly deluged with books on the practise of medicine, both good and bad, and to the credit of the profession be it said that the great majority of them have been unusually good, several of them bidding fair to become almost classical because of the original work bestowed upon them and the care with which they were written. Dr. Anders does, however, recognize the fact that in the present state of medical literature it is impossible to write a book on the practise of medicine without gleaning freely from contemporary works, and he gives credit to the many good books of the time for much of the information which his volume contains. It is to be understood by the reader that Dr. Anders' book is quite as pretentious in size as any of the recent volumes which we have mentioned, and we think that a fair judge will conclude that while it is not superior to some of the recent standards which have been set up for us, it is, at least in some respects, quite equal to them. It is impossible for such a book to present much evidence of originality. One of the points made by Dr. Anders is that there are no less than fifty-six differential diagnostic tables scattered through the work, most of which are of his own compilation, and these he believes will be of considerable value to the student and physician. We also find on reading the book quite carefully that in addition to these differential tables every now and again we gain the benefit of Dr.

Anders' large clinical experience by reading the details of a case or his expression of an opinion based on the cases which he has observed with his own eyes, and to this extent, of course, the book possesses originality. In the face of the books which are already published it seems futile to assert that this one has a large field which it can fill, but we can truthfully say to our readers that if they purchase "Anders' Practice of Medicine" they will at no time have cause to regret their purchase and can rest assured that they have obtained a reliable and trustworthy guide in the important subject of which it treats.

A TEXT-BOOK OF PRACTICAL THERAPEUTICS. With Especial Reference to the Application of Remedial Measures to Disease and Their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., B.Sc. Sixth Edition, enlarged, thoroughly revised, and largely rewritten. Price, \$3.75.

Philadelphia and New York: Lea Brothers & Company, 1897.

The object of this work has been described in earlier issues of the GAZETTE, in the notices which have been given previous editions. The preface of the sixth edition here follows:

"Although the number of copies printed of the fifth edition of this work was almost three times as great as was the case with earlier editions, they have been rapidly exhausted, and the author has been called upon within two years to prepare the manuscript for the sixth edition. The original object of the book was to present the physician and student with a well digested and concise, yet practically useful, statement of the best methods of treating disease. It was written for the reason that the author appreciated as a practitioner and teacher that many of the works upon this subject contain a vast amount of information so compiled as to be almost useless because the reader is forced to discover for himself what is worthy of his confidence. For this reason remedies which are so rarely employed as to be curiosities are not discussed in this volume, and the space so saved is utilized in rendering rational the application of well tried remedies both new and old.

"Many books after appearing in several editions lose a large part of their original value because the statements that have been added are so confused with the original text that its conciseness is destroyed. Recognizing this fact the author has rewritten a very considerable portion of the present edition in order to render the statements in the

text clear and concise. He has also endeavored so to arrange the work that it can be readily used in conjunction with his '*Text-book of Practical Diagnosis*.'

"As this volume is not intended as a year-book for the record of all things in therapeutics, only those measures which have proved useful and reliable in therapeutics are included. For this reason nothing is said of the use of serum in the treatment of many infectious processes in which it has proved itself of little or no avail: for instance, in streptococcus infection or tuberculosis, or in croupous pneumonia."

THE PRACTICE OF SURGERY. A Treatise on Surgery for the Use of Practitioners and Students. By Henry R. Wharton, M.D., and B. Farquhar Curtis, M.D. Profusely Illustrated.

Philadelphia: J. B. Lippincott Company, 1897.

It is always satisfactory to find stated in the preface the exact purpose for which a book is written; this the authors of this work express as follows:

"They recognize the fact that to give a synopsis of the science of surgery in one volume becomes each year a more difficult task, owing to the extension of the field of surgery since the adoption of aseptic methods. It appeared, however, feasible to condense within that limit the information necessary to enable the general practitioner or the student to carry on or begin the successful practise of the art of surgery. It seemed to them that the essential information included: (1) A description of the various injuries and surgical diseases sufficiently full to enable the practitioner to recognize them when met with in practical work; (2) full directions for the treatment of such injuries and diseases as would usually be attended by the general practitioner; (3) a sketch of the treatment of the more difficult conditions, such as would allow the practitioner to advise patients intelligently in obtaining special skilled surgical attention; (4) an outline of the accepted facts and theories of the etiology and pathology of the various surgical affections sufficient to form a foundation for the clinical picture and give directions for the treatment. Even with these limitations the material is so bulky as to require great condensation and the most careful choice of those subjects which were to receive detailed treatment. The authors cannot hope that all their critics will agree with them in the decision of the relative properties assigned to the various topics, but they trust that their practical conclusions will be found conserva-

tive and yet thoroughly modern. They hope that the book will prove a useful guide to the student in the beginning of his work in the complicated science of surgery, and that it may also serve as a ready help in the solution of the surgical problems which confront the busy general practitioner."

As for the fidelity with which the purposes as thus clearly expressed is adhered to, and the general adequacy of the volume, there can be no doubt; it is clear, direct, modern, well illustrated, reliable. The entire ground is covered in a little over twelve hundred pages.

THE JOHNS HOPKINS HOSPITAL REPORTS. Volume VI.

Baltimore: The Johns Hopkins Press, 1897.

The first article in this volume is entitled *Studies on the Lesions Produced by the Action of Certain Poisons on the Cortical Nerve Cell*. To this elaborate study are appended some striking illustrations. The lesions illustrated are those of alcohol poisoning, ricin poisoning, and experimental rabies. The addenda include *Intra-Cerebral Nerve Fibre Terminal Apparatus and Modes of Transmission of Nervous Impulses*; *Asthenic Bulbar Paralysis*.

Under the Report in Pathology are found: *The Pathology of Toxalbumin Intoxication*, by Flexner; *A Bacteriological and Anatomical Study of the Summer Diarrheas of Infants*, by Booker; *Adeno-Myoma Uteri Diffusum Benignum*, by Thomas S. Cullen; *Pregnancy in a Rudimentary Uterine Horn, Rupture, Death, Probable Migration of Ovum and Spermatozoa*; and *Fatal Puerperal Sepsis Due to Introduction of an Elm Tent*, by Cullen.

Of the scientific value of these reports it would be difficult to say too much. They are issued with a profuseness and beauty of illustration and an accuracy and thoroughness of investigation which suggest an enviable disregard of both time and money.

THE NORMAL AND PATHOLOGICAL CIRCULATION IN THE CENTRAL NERVOUS SYSTEM: ORIGINAL STUDIES.

By William Browning, Ph.B., M.D.

Philadelphia: J. B. Lippincott Company, 1897.

The title of this work would naturally lead one to expect a more or less elaborate text-book minutely describing the vascularization of the brain and spinal cord. This, however, is not the intention of the author, his book being based upon experimental and clinical work, and embracing at least in part some of his well known papers upon the subjects con-

sidered. The first chapter is devoted to the examination of the Spinal Efferents for the Cerebro-Spinal Fluid. It is concluded that outlets for the cerebro-spinal fluid exist along the lumbar nerves in the lower animals at all ages, but in the human only during fetal or uterine life. The veins of the brain of the monkey are described in the third chapter. In the fifth chapter the author discusses the arrangement of the Supra-Cerebral Veins in Man, as Bearing on the Theory of a Developmental Rotation of the Brain. There follow some reports of interesting and rare cases, minute directions for lumbar puncture and the removal of cerebro-spinal fluid are given, together with a very comprehensive tabulation of the literature.

The section upon obstructive hydrocephalus is one of special merit and thoroughness, as is also the final chapter, entitled *Apoplexies of the Brain: The Importance of Early Treatment Based on the Differential Diagnosis of the Several Forms*.

This book is commended as embodying the logical deductions of one who has studied in both the experimental and clinical fields.

### LONDON LETTER.

BY RAYMOND CRAWFORD, M.A. OXON., M.D., M.R.C.P. LOND.

Assuming that the end of medical science is the alleviation or arrest of suffering, and not merely to be an instrument of mental evolution, it is remarkable that such scanty attention should be paid to the department of therapeutics. In London we have societies devoted to every other branch of medicine and its sister sciences—to preventive medicine, to pathology, and to clinical medicine—but we possess no therapeutical society. Lancashire has, however, led the way in the establishment of a therapeutical society at Manchester, and perhaps what Lancashire does to-day London will do to-morrow. At the inaugural meeting of the society Professor Leech made some interesting observations and suggestions on the work of a therapeutic society. He attributed the delayed birth of such a society to the fact that therapeutics had been regarded as an integral and inseparable portion of clinical medicine. We are hardly convinced of the sufficiency of this explanation, for the same reasoning is ap-

plicable to preventive medicine and pathology, and yet these departments have not been left out in the cold. The far simpler explanation suggests itself to us that practical therapeutics as at present applied hardly rank as a science, and cannot therefore be the subject of profitable discussion by a society. As Professor Leech points out, the pendulum has swung from one extreme to the other, and whereas *a priori* hypotheses dominated the therapeutics of the early portion of the century, our ideas are now bound in the fetters of practical experience. It is to be hoped that the pendulum is now coming to rest between these two extremes, and that applied therapeutics may be brought into line with experimental pharmacology. Pathology in the last few decades has disclosed the exact nature of so many of the morbid processes which medicine has to encounter, has shown us so much of what we have to do, that we cannot well delay in seeking how to do it. A therapeutic society should certainly conduce to this end by facilitating the exchange of observations and experience of the usefulness of remedies among those who employ them. Collective experience of clinical results is the only check on the fallacious evidence of individual idiosyncrasy. As an instance in point, for half a century practitioners credited the active usefulness of the tincture of conium, made from the dried leaves or ripe fruit, which has now been shown to be absolutely inert; and as Professor Leech remarks, it is not at all clear that there is any justification for our present belief in the tincture prepared from the green seeds. But to get any useful information from collective investigation the procedure must be precise and orderly, and this is best secured within the membership of a society. There can be little doubt of the justice of his conclusion that "it is impossible to get a large number of men who have no great interest in a subject to answer even simple questions with sufficient accuracy to ensure reliable results when the answers are tabulated." On very much these lines the annual report of the Metropolitan Asylum's Board has shown pretty clearly how far and under what conditions antitoxin may be usefully employed in cases of diphtheria; and though a considerable diversity of result is recorded at the different hospitals, this has been almost completely elucidated by comparing the different conditions under which it was employed. In the same way a therapeutic society might do much to restore

order among the chaotic notions that exist in the profession with regard to the animal extracts. The evidence of pathology is pretty clear as to the opposite nature of exophthalmic goitre and myxedema, and yet thyroid extract is used indifferently for the alleviation of each disorder; and worse than this, therapeutic results, when stated with sufficient vehemence or insufficient insight, have been permitted to deform the demonstrative evidence of morbid anatomy. We hope that the good example set by Manchester may be followed elsewhere.

Dr. Sandwith, of Cairo, records a case in which thymol was employed most successfully as a vermifuge; he had used it mainly for the destruction of *anchylostomum duodenale*, but the present case shows its applicability to other parasites. The patient had suffered from *anchylostomiasis* for twelve years, and on admission to hospital was given sixty grains of thymol in two doses on an empty stomach; the same day he passed 523 specimens of *anchylostomum duodenale*, and 55 oxyurides. Five days subsequently a similar dose brought away only three oxyurides, and fifteen days afterwards no worms were passed after the dose, and no eggs were detected microscopically. The characteristic anemia readily yielded to iron, rest, and better food. In much smaller doses we have ourselves been frequently disappointed in the use of thymol as a vermifuge, and it is interesting to learn that one need not regard the pharmacopœial limitations of dosage, a respect for which is engendered by the powerful antiseptic properties of thymol. It would be interesting to know in what form the sixty-grain dose was administered, so as to avoid its undoubted caustic effect.

Dr. Lauder Brunton, in his recently published "Lectures on the Action of Medicines," among much that is chatty and instructive incidentally remarks that "sternutatories are sometimes employed in country practise as substitutes for the forceps in labor." This statement has drawn down on him the righteous indignation of a provincial practitioner, who with the most winning earnestness argues the superiority of the forceps to this perfunctory method of accelerating childbirth. But without carping at the positive pleasure he experiences in the assured and apparent efficiency of the art of forceps traction, we cannot agree with him in classing ergot among the unscientific sternutatories. The teachers of modern obstetrics have done much to bring ergot into disuse, but we fancy

this is merely a reaction against its excessive and unreasoned employment in all cases in years gone by. Dr. More Madden discusses this question in a recent issue of the *Dublin Journal of Medical Science*. He is of opinion that obstetricians have attended too much to laboratory estimates of the active principles of ergot, and too little to the observed results of its clinical use. We are even in the dark as to the number and nature of the active constituents, among which are ergotinic acid, sphacelinic acid, and cornutin. Of these the first named has no action on the uterus; sphacelinic acid is on the other hand an active poison, and by its action on the arteries is responsible for the gangrenous phenomena of advanced ergotism. It is the alkaloid cornutin that is of specific value as an ecbolic; this principle causes waves of contraction in the pregnant and non-pregnant uterus, without inducing a tetanic condition. Dr. More Madden summarizes the alleged dangers of using ergot as: (1) A possible fetical effect; (2) the inducing of irregular uterine contraction such as to favor retention of the placenta; and (3) a toxic action on the mother. The first objection has not stood the test of experience, although such a danger is conceivable if it be used in cases of protracted labor due to persistent uterine contraction. Dr. More Madden supplies an answer to the second and third objections by an abstract of 150 cases in which he had used ergot. Of these patients two died from causes unconnected with labor. In ninety-five of these cases the drug was given before the birth of the child, either for uterine inertia or to prevent hemorrhage, and in ninety-two the child was born alive; that the still-birth of the remaining three could not be ascribed to the ergot was shown by evidences of intra-uterine decomposition. In these ninety-five cases the placenta was naturally expelled in eighty-six, while in only one case was it retained by hour-glass contraction of the uterus, the retention in the remaining cases being due either to morbid adhesions or uterine inertia. In the other fifty-five cases the ergot was given after the birth of the child, either to assist in the expulsion of the placenta or to arrest hemorrhage.

While these figures go far to establish the usefulness of ergot skilfully employed, they do not of course establish the harmlessness of its abuse. On the other hand, from the very fact that the drug has the power of stimulating tonic uterine contraction, it follows that danger to the child may arise, if it

be used before full dilatation of the os, by arresting its circulation. So, too, Dr. Madden is of opinion that if large and effectual doses are given, sufficient to obtain the full physiological action of the drug, we shall have no trouble with irregular uterine contractions. His general conclusions are that ergot may in some cases be given in the first stage, before full dilatation of the os, when uterine inertia is endangering either the mother or the child; in the second stage it may be similarly used to promote uterine contraction, provided the presentation be normal, and no other impediment to delivery exist; in the third stage it may be used to assist expulsion of the placenta, if retained from uterine inertia; and in all stages for the prevention or arrest of hemorrhage. After labor it is useful in arresting after-pains by the expulsion of clots, and in promoting full involution of the uterus, especially in multiparæ in whom the muscular contractibility of the uterus is enfeebled. Lastly, he suggests that it may lessen the liability to the invasion of septic organisms by sealing up the uterine vessels. For use during or immediately after labor he prefers the official liquid extract, and gives two or three drachms by the mouth, supplemented if necessary by a drachm or two by gluteal injection. For the various purposes for which he uses ergot during the lying-in period, he has found drachm doses of liquid ergot, along with tincture of nuxvomica and citrate of iron and quinine, most serviceable.

A great deal of literature has been recently devoted to the treatment of ulcerative endocarditis by antistreptococcic serum, but we fancy that the general trend of physicians is towards dropping this line of treatment. Where such a multiplicity of organisms may be the efficient cause, and where examination of the blood so often supplies a simple negative, it is impossible to forecast with what organisms we have to deal, although streptococci usually predominate; nor on the whole have clinical results done very much to encourage its further use. It is true that from time to time cases are brought forward in which a favorable issue has seemed to depend upon it, and such a one is recently recorded by Dr. Washbourn from Guy's Hospital. In this case there could be no real doubt of the correct diagnosis, as a murmur of pulmonary regurgitation developed under observation in the course of several weeks of ill-defined septicemia with no obvious origin. For nearly two months the patient was given a daily

dose of twenty cubic centimeters of the serum, when the dose was gradually diminished for a fortnight, and then omitted. The pyrexia that prior to treatment with serum had been markedly septic, ranging daily as high as  $102^{\circ}$ – $105^{\circ}$ , with rigors and profuse perspiration, had completely disappeared in a fortnight, and the patient, who had hitherto steadily lost ground from day to day, at once rallied, so that in the course of a month she was practically well. The treatment extended over a period of nine weeks, during which time the patient received 1030 cubic centimeters of serum in fifty-nine doses, and in spite of the enormous amount employed the only ill effect was a transient urticaria. The pulmonary bruit still persists, but the whole septic trouble is clearly at an end.

We have followed with interest some correspondence in the medical journals on the Aachen treatment of syphilis. The ball was set rolling by a statement of the famous Dr. Brandis "that the inunction cure . . . in combination with the use of the Aachen waters is well known to be one of the strongest, if not the most powerful, antidote to the syphilitic poison." To this statement Arthur Cooper, of London, demurs, from a long experience of syphilis treated at Aachen and elsewhere. We agree with him that "provided the patient does as he is told, and that due attention be given to details both as regards his treatment and his mode of living generally," equally good results can be obtained in London as in Aachen. But this is the whole crux of the position, as we can testify from a limited experience of patients submitted to the Aachen cure. We should say that there is no special advantage in sending to Aachen a patient of well ordered life, who will carry out scrupulously and to the letter the directions we give him. To any one who has seen the Aachen treatment there will be little doubt that the skin is the proper channel for the administration of mercury. To the English visitor the patron saint of Aachen is not Charlemagne, but one or other of the established "frotteurs," the cheery Wilhelm, or the philosophical Franz. In private practise at home the inunction for one reason or another, usually for sake of secrecy, devolves upon the patient himself, and here inunction is at a distinct disadvantage: the patient gets less, and his habiliments more, and the curiosity of the chambermaid is aroused. Moreover, the daily hot soak at Aachen is undoubtedly of value in preventing the local eruptions that are so

common with even the most careful and well distributed mercurial inunctions; but we do not for a moment believe that there is any special value in the sulphurous waters. It is the story of Naaman over again: the continental Abana and Pharpar exercise a superior charm to the domestic bathroom; and in the one case we can count upon enthusiastic compliance, in the other on the perfunctory dallying with the systematic hot bath. At Aachen the hot bath immediately precedes the inunction and certainly facilitates the absorption of the mercury, but at home the bath is looked upon merely as "a bath of purification," and once a week follows the inunction. In mercury we have to all intents and purposes a specific for syphilis, and as physicians we have only to ensure that it is given in the right way, at the right time, and in the right place; and until we can introduce some such center of treatment into England, we believe Aachen to be that place. We believe that Harrogate supplies all the essential requirements of such a center, if only there were superadded a system of regular meals and of regular living, to keep at bay the evil spirit of forgetfulness that is the barrier to success in treatment.

#### PARIS LETTER.

---

BY A. R. TURNER, M.D. (PARIS).

---

A few days ago the non-medical papers announced the arrest of a young physician practising in the east end of Paris, beyond the Faubourg Saint-Antoine. He was charged with gross malpractise in an obstetrical case. Having been called in by the midwife in charge he had endeavored to perform craniotomy, but so unsuccessfully that the patient had succumbed to the effects of lacerations of the soft parts. Curiously enough, a diary which the unfortunate young man had kept fell into the hands of the journalists, and from it some idea was obtained of his previous existence and its struggles. After taking his degree, Dr. Laporte—such was his name—served some time as surgeon on the ships of the Compagnie Transatlantique. Leaving their service with a small amount of money accumulated by economy while in their employ, he hired an apartment in one of the wealthier quarters of Paris and waited for patients. However, none came, and his funds being soon exhausted he was obliged to remove to one of the most obscure portions of the city, where he hired an apart-

ment or lodging at 350 francs a year (\$70). Dr. Laporte caused himself to be inscribed on the list of physicians for the "Assistance médicale de nuit," of which I have before spoken, and on the small fees thus obtained and what he could earn in other ways among a population which resorts chiefly to the hospital for gratuitous advice, managed to support himself.

The case to which Dr. Laporte was called, and in which an unsuccessful result led to his arrest, was a case of childbirth in which death of the child had occurred owing to the prolapse of the funis. The head was likewise too large. Dr. Laporte made three attempts with the forceps, but not succeeding, determined to perform craniotomy. To do this he asked for the implements used by the husband, an artisan, in his trade. These he employed, but unsuccessfully, and the woman, who was almost exhausted, expired not long afterwards. All this, it may be said, took place at an advanced hour of the night. At the autopsy a lacerated wound of the bladder was found, with other lesions due to violence.

The police authorities caused Dr. Laporte's arrest, and for several days, notwithstanding the protests made by several of the medical associations and by some of the most prominent medical men in Paris, bail was refused. Only recently has Dr. Laporte been allowed out on bail furnished by the president of one of the syndicates of physicians practising in Paris. Another medical society in Paris has sent a certain sum of money to Dr. Laporte, and other societies have voted resolutions in his favor.

What strikes the physician as most dangerous is that henceforth an embarrassing case in which some extreme resolution should be taken will be treated by expectation only, if an unsuccessful result is likely to be followed, not only by a lawsuit, as happens too frequently in all countries, but by imprisonment previous to any verdict.

At a recent session of the Academy of Medicine Dr. Lancereaux communicated to the society an account of a case of renal ectopy in which the displaced kidney returned to its correct position at two different times under singular circumstances. The patient was a woman in whom in 1894 a displaced kidney was discovered in the right flank. On undertaking a long journey by rail the symptoms vanished, and on examination the kidney was found to have resumed its normal position. In 1896 the same symptoms were observed, and the kidney was

found to be once more displaced. Another long journey by rail once more caused its return to its normal position.

Not long ago Dr. Carrasquilla, of Venezuela, claimed to have treated with successful results some cases of leprosy by means of horse-serum obtained from animals into which serum obtained from lepers had been injected. In a report made to the Academy of Medicine Dr. Hallopeau gave the results of his experiments at the Hôpital Saint Louis. In the first place he complained that the serum contained various bacteria, proving that it had been obtained without the necessary precautions as to cleanliness. It seemed, however, to be well borne by the patients. Both its local and general reactions were moderate, but it did not seem to produce any specific effect, as it neither prevented fresh lesions from appearing, nor were any ameliorations observed which had not at other times occurred spontaneously. However, notwithstanding the unfavorable results obtained thus far it was his intention to carry out still further experiments in the sero-therapy of leprosy.

Dr. Denigis, of Bordeaux, recommends the following solution for antiseptic purposes as not injuring surgical instruments made of iron, steel, or nickel, while possessing the advantages of other mercurial compounds: Distilled water, 1 liter; cyanide of mercury, 2 to 5 grammes; borax, 10 grammes, or carbonate of sodium 14 grammes.

#### *SOLANUM CAROLINENSE.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: In your September number, on page 622, in an article from the May number of the *University Medical Magazine*, you refer to the use of *Solanum carolinense* in the treatment of epilepsy, first recommended by Napier. But I think some credit is due to Dr. F. Peyre Porcher, who pointed out its value in convulsive diseases in his book, "Resources of the Southern Fields and Forests," which was published in Charleston in 1863, by order of the Surgeon-General, Richmond, Va. Yet when the Surgeon-General was publishing his list of "Indigenous Remedies for Field Service and Sick in General Hospital," *Solanum carolinense* was not included amongst those published in the *Confederate States Medical and Surgical Journal*.

Yours truly,

GEORGE FOY.

### REMARKS ON THE SURGICAL TREATMENT OF GOITRE, WITH A REPORT OF SIX CASES TREATED BY OPERATION, AND ONE CASE CURED BY SPONTANEOUS SUPPURATION.\*

BY EDWARD MARTIN, M.D.,  
Clinical Professor of Surgery, Women's Medical College;  
Surgeon to the Philadelphia, Howard, and  
St. Agnes Hospitals.

Since it is my intention in this communication to consider goitre solely from the operative standpoint, this question having been

chosen for presentation because six cases on whom I performed partial excision happen to be in the city and are waiting to appear before you, a discussion of the etiology and pathology of the subject is unnecessary.

Clinically goitre may be classed under three general headings:

1. Tumors either small or large, solid or cystic, which occasion neither local nor general symptoms, and are annoying only because of the deformity they cause.

2. Tumors which by mechanical pressure on important structures cause pronounced local symptoms. The chief of these are pain, tenderness, dyspnea, alteration of voice, and cephalic congestion. The local symptoms

\*Read before the Philadelphia County Medical Society.

caused by these tumors have no necessary relation to either the size or consistence of the growth. In this group there is added to the deformity more or less disability and suffering of intermitting intensity, and a distinct element of danger.

3. Tumors which, either with or without local pressure symptoms, are associated with profound systemic disturbances, the chief of which are aggravated neurasthenia, tachycardia, tremor, insomnia, and exophthalmus. In this group the symptoms are crippling and usually progressive; the whole mentality is changed. The growth may be small or large. Contrary to the generally accepted opinion it is not necessarily more vascular than the solid and cystic goitres of the first two groups. Nor histologically can there be detected any difference in the processes of hyperplasia, infiltration, and degeneration characteristic alike of the exophthalmic, the solid, and the cystic goitres. Even symptomatically there can be drawn no sharp distinction, since it is common enough to observe an ordinary goitre in the course of its growth gradually become associated with symptoms of Graves' disease.

In most of the cases I shall present some of the symptoms of beginning systemic involvement were present, particularly the rapid pulse, sleeplessness, and neurasthenia. In two the exophthalmus though slight was distinct; in none were the general symptoms so pronounced as to justify the name of exophthalmic goitre, though I believe this term as implying a morbid process different from that of ordinary goitre is misleading.

Of the three clinical groups of thyroid enlargements above described, all are proper subjects for surgical intervention, provided a careful trial of medical means, including electricity, has proven unavailing.

In the first group of cases—*i.e.*, those in which the tumor troubles only because it is unsightly—operation usually may be deferred when the growth is stationary or retrograding and when it is not a source of constant mental discomfort to the patient. It is hard to realize how wearing this discomfort may become; to hypersensitive women these growths often assume exaggerated proportions and repulsive features, which they think not only impossible to be hidden by the most skilful draping but disgusting to every one with whom they come in contact. This state of mind entails so much suffering that I believe it in itself is a sufficient indication for operation, even

though the goitre be without symptoms and non-progressive.

When tumors of the first group are steadily increasing in size the operation should be undertaken promptly, since the increase is likely to be progressive and to result in the formation of a growth difficult to remove because of its size or because of the development of pressure symptoms which may make the administration of an anesthetic dangerous.

But one case of those I have shown can be classed in this first group: Mrs. M. wished the tumor removed because it was unsightly and gave her a sensation of dragging and weight. She suffered from neither pressure nor toxic symptoms. She expresses herself as well satisfied to be rid of her growth, which wore upon her because of its fancied unsightliness and apparent inevitableness.

All tumors of the second class—*i.e.*, giving rise to local or reflex pressure symptoms—should be subject to prompt operation, and when there is recurrent dyspnea the indication for operation is urgent.

In tumors of the third class the beneficial effects of surgical intervention are so striking and the mortality following operation is so slight that on the failure of medical treatment there should be no hesitation in advising ligation or partial thyroidectomy.

The *diagnosis* of goitre is usually a simple matter, the tumor springing from the anterior aspect of the neck, being attached to the larynx and when small moving with this structure; when aberrant, as in the case of retrosternal goitres, having a pedicle springing from about the normal portion of the thyroid. When very large the tumor presents a typical appearance, which if taken in connection with the history of the growth is sufficiently characteristic.

Malignant degeneration has in its early course no distinguishing clinical features. The rapidity of growth is often suggestive, and in the case of carcinoma its conformation, the infiltration of surrounding structures, glandular metastasis, and the early development of pressure symptoms would be diagnostic, but not at a time when the patient could be helped by intervention. A causeless, comparatively rapid, relentlessly progressive solid nodular or smooth rounded painful tumor growing from the thyroid of a man over forty years old should always suggest the possibility of malignant degeneration. Malignant degeneration in women is less common.

The *prognosis* of untreated goitre is difficult to formulate. I have found no statistics bearing on this point, but would venture to express the opinion that when the thyroid is once permanently enlarged there is a tendency toward steady growth, and that a patient with a small goitre which is annoying only because of deformity can count as a rule upon a progressive increase of this deformity, so slow that it is noticeable only from year to year—and upon a more or less pronounced chronic neurasthenic condition due to the growth and only to be cured by its removal. Exceptionally the goitre disappears or remains stationary. In a small percentage of cases it grows rapidly, causes more or less pronounced pressure symptoms, and is associated with an aggravated neurasthenia, with dyspnea and heart irregularity especially well marked. In a smaller percentage of cases the disturbance of the vasomotor mechanism of the thyroid circulation becomes especially noticeable, and the pulsating tumor is associated with the characteristic symptoms of exophthalmic goitre. In a still smaller percentage of cases the symptoms of cachexia thyreopriva develop. Exceptionally the enlarged thyroid undergoes malignant degeneration.

It is obvious, then, while the prognosis as regards life is favorable, that the patient who carries a goitre is likely at the best to be subject to steadily increasing deformity and a particularly harassing form of chronic invalidism unreachable by any form of therapeutics; at the worst this patient is exposed to a painful, absolutely crippling, fatal malady.

The treatment of goitre is as a rule relegated to the physician. I believe the usual inefficacy and the possible danger of the iodide treatment is now generally conceded. It is clearly shown that by a general bracing hygienic, climatic, and electric treatment many cases of goitre, particularly those of the exophthalmic variety, may be greatly benefited—sometimes they are cured.

The most promising internal medication is thyroid extract, which, though it has not worked a revolution in the therapeutics of goitre, may be expected to cure a small percentage of cases.

Bruns states that in young children complete recovery is the rule, the remedy being continued with intermissions in case palpitation, diarrhea, headache and tremor denoted hyperthyroidism. But few adults recovered, and even in older children the enlarged thyroid did not shrink to its normal size.

This treatment is contraindicated in Graves' disease, since the symptoms of the affection are supposed to be due to a system supersaturated with the normal or perverted thyroid secretion caused by increased blood-supply and hyperplasia of secreting cells.

Serafine (quoted by *Revue de Thérapeutique*, July 15, 1897) states that treatment of goitre by thyroid gland is best adapted for the form known as struma parenchymatosa. Definite cure is rarely observed and only in young subjects. The results are satisfactory in sixty-three per cent. of cases, the goitre lessening in size. In thirty per cent. of the cases the treatment is absolutely valueless. When goitre has undergone secondary degenerations, such as colloid or cyst formation, the treatment is useless. The effect of treatment is manifested almost immediately, and the dry thyroid is more potent than other forms of the gland. Thyroid is not indicated in Basedow's disease excepting at the very beginning of the affection; when the symptoms are pronounced, not only is the treatment useless but even dangerous. The therapeutic effects are transitory, hence the thyroid extract should be given from time to time.

The operative treatment should properly include galvanopuncture and injection, since it is essential that these procedures should be carried out with attention to the principles of surgical cleanliness. Neither of these procedures requires the administration of an anesthetic, and except in the cases complicated by dyspnea confinement to the bed or even to the house is not an essential part of the after-treatment. Both methods may be indicated when because of a patient's dread of the knife a more radical treatment cannot be adopted. Both have recorded to their credit many cures.

The electric needle can scarcely be expected to prove serviceable when the tumor is made up of one or more large cysts. When the growth is solid its action has proven most satisfactory. The method is not without pain, is followed by inflammatory swelling, and usually requires a treatment prolonged over several months.

Injections of iodine or of iodoform emulsion are probably about as safe as a cutting operation, and provided the treatment is continued weeks or even months, the injections being repeated every third or fifth day, it is likely to cure recent parenchymatous enlargements—fibrous and cystic goitres are not amenable to this treatment.

Brunet records fifty-nine cures in eighty-eight cases treated by iodine injections. Holmes records 111 cures of 183 cases treated, and seventeen of these were exophthalmic—in but thirty-three cases were the results negative. Five to ten drops of iodine tincture were injected at each treatment. A number of deaths are recorded as an immediate result of iodine injection, usually attributable to embolism.

Iodoform emulsion was used by Garré in 140 cases without a fatality and with uniformly good results. About twelve injections were given in each case, the injections containing one grain of iodoform in fifteen minims of a mixture of ether and olive oil.

The mortality of the operative treatment, by which is meant enucleation of cysts or partial resection of the enlarged thyroid, has fallen from over forty per cent. to almost the vanishing point—less than one-half per cent. in over 1500 cases operated on by four surgeons. In 200 and odd cases collected from medical literature by Dr. Francis Patterson and reported by over thirty surgeons the mortality was above three per cent.

*Operative Technique.*—Of the various incisions practised in the removal of the diseased thyroid gland, the transverse is to be preferred since it gives free access to the operative area, is more accurately apposed in suturing, and after healing leaves a much less conspicuous scar. Kocher, whose teaching on this point has been too little regarded, has shown that in a given region of the body two incisions vertical to each other exhibit a varying retraction of the margins; if one gapes widely the edges of the other are apposed even without the aid of sutures. He holds the difference in cicatrization after incision, with or against what Lange calls cleavage lines, is so important that it is serviceable to indicate what may be called normal incisions for every region of the body. These show for that particular region the cleavage line of the skin and at the same time are so placed as to avoid the course of important structures. Especially in the operations for struma Kocher has demonstrated that the cicatrices after normal incisions become so faint in the course of time that they are hard to recognize, while cicatrices following incisions in different directions, especially on the neck, may often cause great deformity by contraction of the folds. The normal incision for the anterior surface of the neck in its upper part is transverse; in its lower part transverse with a slight curve down-

ward. This incision is carried over the most prominent part of the goitre from about the mid-width of one sterno-mastoid muscle to a similar point on the opposite side of the neck. Where the goitre is large and dips well into the chest the angular incision is indicated. This begins over the bulge of the sterno-mastoid muscle at the level of the thyroid cartilage, runs transversely in the direction of the wrinkles to the midline of the neck, and then downward to the suprasternal notch or the middle of the manubrium. After division of the skin and platysma the fascia uniting the sterno-hyoid and sterno-laryngeal muscles on each side is divided and these muscles are separated, exposing the tissues lying below, or are cut completely across. Kocher advises that a portion of their continuity in length should be preserved. The sterno-mastoid muscles are well retracted, as are also the sterno-hyoid and the sterno-laryngeal, if they have not been completely divided, and the fibrous capsule which still invests the goitre is carefully cut through until the surface of the tumor is reached. This is usually brownish or bluish in color and often has enormous veins ramifying over its surface. By means of the fingers and gauze sponges the fibrous capsule is separated from the tumor, any veins passing between these two structures being doubly ligated as they are encountered until the lobe on one side can be lifted forward, thus exposing its posterior surface; the inferior thyroid vein and artery can then be carefully isolated and ligated. The upper or lower portion of the lobe is then turned out, depending upon which is most readily freed from its usually slight adhesions. Vessels are secured between double ligatures and ligated. Beneath the isthmus a ligature is passed by means of a strong aneurism needle. The tumor, the blood-supply of which is thus absolutely under control, is either removed completely, or that portion which is diseased is cut away, leaving the healthy tissue. In the latter case the diseased nodules and cysts are enucleated from the portion of the goitre which has been freed, pressure and traction upon the isthmus or ligature readily controlling bleeding. The tumor of the opposite side is treated in a similar manner. The method just given is essentially that recommended by Kocher, whose immense experience in this line of work entitles him to speak with absolute authority. Preliminary ligation of the thyroids is often not necessary before enucleation of superficially placed cysts.

In the cases which I have shown the transverse incision slightly convex downward gave ample room. Where the growth was particularly large the external laryngeal muscles were extremely thin and were divided completely across, in some cases being reunited by sutures. The freeing of the goitre from its capsule was greatly facilitated by dry gauze sponging, the veins being secured by the double ligature as they were encountered and every effort being made not to tear or wound the tumor in any way. The upper cornua of the tumors were turned out first, the superior laryngeal vessels being secured with double ligature. The main operative difficulty was found in overcoming adhesions posteriorly which seemed to fix the tumor to the deep cervical fascia covering the prevertebral muscles. The inferior thyroid arteries were carefully isolated before ligation, lest the recurrent laryngeal nerve should be injured, and when the portion of the thyroid lying in relation to this nerve seemed healthy it was cut across and left in place, thus effectually guarding against injury of this nature.

The bleeding during the operation, excepting in two cases—one in which enucleation of the cyst was attempted without previous ligation, and the other in which traumatic inflammation rendered freeing of the tumor unusually difficult—was trifling. In the case in which enucleation of the cyst was attempted it was so severe as to threaten death, but the patient made an absolutely uninterrupted convalescence. This case (my first) was ill suited to the operation selected, since the cyst walls were degenerated, calcareous, and adherent, and the growth was extremely vascular. Enucleation should have been preceded by ligation.

In all the cases there was marked post-operative oozing, always, I believe, from the cut surface of the thyroid and probably venous, and incident to congestion due to ether-vomiting. These oozings were so marked that they led me to employ drainage, since twice when this was omitted and the wound healed by first intention a cyst formed, which broke down in about ten days, discharging clots and bloody serum.

Dyspnea following operation was noted in two cases. In one of these the operation was extremely difficult because of previous traumatic inflammation, requiring for its completion nearly three hours. In the other the tumor was unusually large, but the operation was completed without difficulty. In both in-

stances the dyspnea was alarming but transitory. Oxygen inhalations seemed to be particularly efficacious. I believe this dyspnea to have been due to either irritation of the recurrent laryngeal nerve or more probably to laryngitis and trachitis caused by mechanical injury to the parts and disturbance of circulation.

In all the cases there was left as much apparently healthy gland as would equal at least two-thirds of the bulk of the normal thyroid. In one case there had been a three-months' treatment by electricity applied by a practitioner who was thoroughly familiar with this method. The scars resulting from this treatment will in a year's time be far more conspicuous than that made by the cutting operation. It was absolutely inefficacious in so far as reducing the size of the growth is concerned. This was an instance of cystic and solid goitre. At the seat of electrolysis the adhesions were dense, and the limiting fascia was separated from the goitre somewhat less easily than is ordinarily the case. It is noteworthy that in none of the cases was there a history of goitre in the family; in none is it possible to trace any causative factor. The three sisters are of Scotch-Irish-Welsh extraction. There is no case of goitre in the family, no goitre in the families of those with whom they were brought up, and in all the disease in its slightest form was noticed in early childhood.

It is clear from the figures I have quoted that the operation of partial thyroidectomy or of enucleation so little threatens life that its performance may be advised even though there is no more pressing indication for it than for the relief of a distressing deformity.

The common operative dangers—suffocation and hemorrhage—if properly guarded against, are slight; the cardiac disease so commonly associated with long-standing goitre and the pronounced anemia characteristic of marked Graves' disease may, however, make the patient especially susceptible to both shock and hemorrhage, while marked dyspnea always renders anesthetization particularly dangerous. This last complication is usually relieved promptly by dividing the deep cervical fascia and turning the goitre forward; though it must be remembered in subsequent manipulations that the tracheal rings may have suffered pressure absorption and the larynx may readily be kinked or compressed. Laryngotomy or tracheotomy and the placing of long flexible tubes of large caliber in the larynx are sometimes necessary.

The immediate sequels of operation may be: thyroid intoxication, usually transitory; free venous oozing, readily controlled by pressure; consecutive hemorrhage, requiring opening of the wound; dyspnea, due to mechanical handling of the larynx and trachea and in part no doubt to irritation of the recurrent laryngeal nerve, relieved by oxygen inhalation; sepsis, to be provided against by drainage, gauze tampons being employed when an accident during the course of operation, such as the patient vomiting into his wound, leads the surgeon to expect infection.

The remote effect of the operation, provided the portion of the thyroid left after removal of the diseased part should undergo degeneration or should prove physiologically inapt, is myxedema or cachexia strumapriiva, now happily readily controlled by thyroid extract—thus enabling the surgeon to perform a complete operation in malignant cases. In about one per cent. of cases the growth recurs, requiring a second operation.

With the operative dangers so well under control, the percentage of radical cure so high, and the ultimate ill effects so entirely avoidable, it is difficult to understand why partial thyroidectomy is not more popular. Dr. Patterson has collected from the reports of five hospitals in this city—namely, Jefferson, Pennsylvania, University, Presbyterian, and Episcopal—the statement that in the last ten years there were treated in these institutions, usually in the out-patient departments, one hundred and eighty-two cases of goitre. Five were operated on, with one death.

It is evident that but a very small number of goitre cases present themselves for treatment, because of the popular belief that the affection is beyond help except at a grave operative risk; nor is this belief confined to the laity. I have tried to show that the operation is a safe one and that the results are as satisfactory as those from any formal procedure in surgery; and it is in the hope that other patients similarly afflicted may seek relief that these seven patients present themselves to you to-night.

The first case is one of enucleation with hemorrhage:

CASE I.—Mrs. Frances R., aged thirty-three, native of Austria, comes from a region in which goitre is common, although no member of her family has been thus afflicted. When she was a schoolgirl she noticed there was something the matter with her neck, but no distinct tumor was formed until ten years

ago, when she was carrying her first child. Since that time it has grown slowly but steadily. In the last two years she has been subject to attacks of violent dyspnea, many times waking her at night. The tumor varied slightly in size from time to time and would often give her much pain. The head seemed to be full of blood and she suffered from attacks of vertigo. She was subject to most distressing paroxysms of cardiac palpitation.

I operated on her May 13, 1896. The goitre proved to be cystic, involving mainly the left lobe. I endeavored to enucleate the larger cyst, which was about the size of a fist, without previously securing the vessels. The walls of the cyst had undergone calcareous degeneration, were densely adherent, and the bleeding was rapid, severe, and difficult to control. Nearly the whole of the right lobe and a portion of the isthmus were finally removed, bleeding was controlled by hemostats and packing, and the patient was returned to her bed in an extremely exsanguine condition. The pulse was so weak and rapid that I should have performed intravenous saline injection but for the fact that I had recently known of two cases which suddenly died while this procedure was being carried out. She reacted promptly and was sent home on the eleventh day, her convalescence having been uncomplicated.

CASE II.—Mrs. W.; family history entirely free from goitrous trouble. She is of Irish parentage and has always had enlargement of the throat and neck, which she thought was due to bad-shaped throat. The lump has gradually grown and has caused pain. She is short of breath at times; trembling, very nervous. The tumor was larger than the fist, but was not lobulated.

Operation January 13, 1897. The growth was exposed by transverse incision and removed, with the exception of the upper and middle portions of the right lobe, which seemed healthy, although enlarged. The tumor was an example of exaggerated glandular hypertrophy, extremely vascular, and tightly adherent. The wound was closed by percutaneous suture and entirely healed in a week. Three days later it broke down, discharging a considerable quantity of bloody serum. This opening very shortly closed. There was enough of the right upper lobe left in this case to result in some permanent deformity, but the condition was so much better than before that the patient does not object to this. Her general nervous condition is no better than before operation, but

there are other factors contributing to that. She expresses herself as well satisfied with the result.

CASE III.—Miss Sarah B., aged thirty-one, has always been in good health since infancy; thought her neck peculiar in shape. First noticed a distinct lump when she was ten years old; since then it has been gradually growing. Under a course of iodide it was somewhat diminished in size, but again increased on stopping the medicine. She took many drugs, but nothing helped in the least. She suffered at times from palpitation of the heart and dyspnea, and always had a feeling of obstruction in the neck. For the last three years has had singing in the ears and fulness in the head. As a result of violent straining, such as efforts at vomiting, the goitre becomes extremely tender and increases in size. Lately it has grown more rapidly than ever before. The whole front of the neck is occupied by a swelling somewhat larger than the two fists and extending downward well behind the clavicles. There is no pulsation or bruit. Operation was performed in the early part of July, 1897, the usual transverse incision being made and the greater portion of the isthmus and the upper part of the left lobe being allowed to remain. The patient recovered promptly and completely from operation and with very little hemorrhage. The enucleation was not especially difficult. The goitre was solid and cystic, this latter process, however, having developed but slightly. Since operation her neurasthenic condition has completely disappeared.

CASE IV.—Mrs. P., aged thirty-three, in early childhood thought her neck was peculiarly shaped. There was no goitre or tumor history in the family. She noticed a lump when carrying her first child. She has had four children, and since the birth of the last the goitre has grown somewhat rapidly. She cannot wear anything tight about the neck, suffering great pain therefrom, which is referred to the back of the head. She has cardiac palpitation and is short of breath. She suffers from tremors at times. Children are well. There was a lobulated mass with a median transverse furrow producing very marked deformity. Operation was performed August 1. Stripping of the deep capsule was somewhat difficult, and there was more hemorrhage than is usual. Both lobes were enlarged, together with the isthmus. The extension seemed to be upward and downward; the lower borders of the growth passed

slightly below the lower border of the clavicles. The right lobe was removed entirely, the upper and middle portion of the left lobe being taken away, and from the isthmus and lower portion of the left lobe were enucleated fifteen or twenty cysts and adenomatous nodules. The wound was closed by percutaneous suture and drained. The patient made an uninterrupted convalescence and suffered so little inconvenience that for the first three days she could scarcely believe that the tumor had been removed. She is now absolutely well and sleeps well at night—the first time for years.

CASE V.—Mrs. Walter M., the mother of three healthy children, referred to me by Dr. John H. Musser, noticed twelve years ago a growth at about the mid-anterior aspect of the neck on the right side. There is no history of tumor in the family. This growth gradually increased in size, and with especial rapidity during the periods of gestation. The only inconvenience caused by it was a sense of weight and dragging and very obvious deformity; also at times there was slight shortness of breath. Never suffered from palpitations, pains, or aches; has not lost weight excepting during a period of thyroid treatment, when she lost rapidly. The tumor formed a mass about the size of two fists, most prominent at the right side, extending well down to the clavicles. She had in 1889 two months' treatment by the electric needle without deriving benefit therefrom.

Operation was performed in May of this year. The entire right lobe, extending well down behind the clavicle, part of the isthmus, and the upper portion of the left lobe, were removed. The lower portion of the left lobe and isthmus were not interfered with, since these portions of the glands seemed healthy; they perhaps slightly exceeded in bulk a normal thyroid. The portion removed was typically cystic. The wound was closed without drainage by percutaneous suture. There was very little loss of blood. The operation was completed in forty minutes. The night following operation the patient complained greatly of dyspnea and pulse hurry, and the face became greatly congested. This was relieved by oxygen. The following day she was given a bed-rest and the bandages were loosened. Thereafter she had no trouble; the wound healed promptly.

CASE VI.—James O'K., referred by Dr. Barton C. Hirst; laborer; single; aged thirty; Irish parentage. No goitre in the family. He first noticed a lump in his neck ten years

ago. Since then it has been slowly increasing in size. In the last two years it has given him pain when he stooped or lifted. He has not suffered from palpitation, shortness of breath, or profuse sweating. Six days before I first saw him, in the course of a fight he was seized by the throat, since which time he has suffered intense pain, referred to the left side of the neck and running up to the occiput.

The goitre markedly increased in size; the overlying skin was hot and slightly edematous. The growth was somewhat larger than a full-sized coconut; it extended to below the sternal notch. It was exposed by transverse incision, and its overlying fascia was found tightly adherent. Its lower extremity extended fully two inches behind the sternum, and it was fastened so tightly to the deep cervical fascia overlying the spinal muscles behind the trachea and esophagus that its dislocation outwards was a matter of extreme difficulty. This was finally accomplished, and the entire gland with the exception of a portion of the left lower lobe about the size of a normal gland was removed. Section showed numerous recent hemorrhages into the goitre and into cysts which it contained. It was the ordinary parenchymatous variety, and excepting for inflammatory adhesions did not present serious difficulties in removal. The patient made an uninterrupted recovery.

The following was a case of spontaneous cure by suppuration:

CASE VII.—Miss Annie R., aged thirty-three, free from goitrous family history, first noticed a lump in her neck four years ago. This as far as she knows was causeless, gradually grew to about the size of an egg and gave her no inconvenience, except when she wore clothing which was tight about it. She noticed, however, that she was becoming progressively more short of breath, suffered from frequent paroxysms of palpitation of the heart, and became extremely nervous. Also she had recurrent headaches which were severe and persistent, and she felt as if her eyes were bulging from her head. On June 7 the goitre became tender, painful, and enlarged without obvious cause. These symptoms increased for six days, when the tumor had reached the size of a cabbage head, and she felt so prostrated that effort of any kind seemed impossible. When she presented herself at the hospital June 15 her evening temperature was  $99\frac{1}{2}^{\circ}$ , the respirations were 98, and her pulse 120. The next evening the temperature had risen to  $101\frac{1}{2}^{\circ}$ . The whole front of the neck was occupied by a tender,

edematous, fluctuating swelling, evidently an acute inflammation of a cystic goitre. This was incised and a half-pint of sero-pus containing broken-down blood-clot was evacuated. The tumor was drained and continued to discharge for two months. For three days the temperature, pulse and respiration were normal, and from that time the patient has not suffered from palpitation, headache, nervousness, or any of the symptoms which were so pronounced during the period of the rapid growth of the tumor. She expresses herself as being absolutely well.

*THE INFLUENCE OF DIGITALIS ON THE  
HEART MUSCLE WHEN THE DRUG  
IS ADMINISTERED FOR A LONG  
PERIOD OF TIME.*

---

By H. A. HARE, M.D.,

Professor of Therapeutics in the Jefferson Medical College  
of Philadelphia;

---

*WITH A MICROSCOPICAL STUDY AND  
REPORT.*

---

By W. M. L. COPLIN, M.D.,

Professor of Pathology in the Jefferson Medical College.

---

This paper is based upon a series of experiments designed to determine whether digitalis when administered over a considerable period of time actually increases the development of the heart muscle. There is probably no drug which has been studied more thoroughly at the bedside and in the laboratory than digitalis. Ever since its employment by Witherington and his classical reports upon its clinical uses, clinicians have relied upon it as one of their most valued medicaments. Particularly is this true in diseases of the heart in its valvular forms when compensatory hypertrophy has not taken place by natural processes. Laboratory investigators have studied it also so exhaustively by every means and form of apparatus that we know something of its physiological effects as produced by the administration of single and multiple, or large and small, doses when they are given within a period covering a few hours. While we know certain facts about its acute effects, if I may use such a term, we know little or nothing of what might be called its chronic influence over the heart muscle itself. It is true that a multitude of clinical observers have found the prolonged use of this drug in proper doses to produce an increase in the force of the apex beat of the heart, an increase in arterial pressure, and a slowing of

the pulse-beat, but though these effects are explained by the known physiological influence of the drug the question as to whether the continuous use of digitalis really strengthens the heart has been undecided. By the term strengthen I do not refer to a temporary increase of power produced by stimulation such as follows the use of alcohol or ammonia, but a condition in which by reason of increased muscular development the heart is actually more or less permanently increased in its muscular development and ability to do any extra work which may be thrown upon it. With the experiments made to determine whether digitalis increases the size and force of the pulse wave by influencing systole or diastole I shall not deal, nor will I speak at this time of the effects of the drug upon the nervous supply of the heart and the trophic influences which govern its nutrition, although it is probable that by these influences the effects obtained by its use are in part brought about.

When digitalis is given to a patient with cardiac disease and death takes place, the post-mortem examination usually reveals an increase in the development of the heart muscle, and it has been customary to attribute this solely to the effort made by the system to establish compensation by hypertrophy. The experiments about to be detailed would seem to prove that the increase in muscular development may be in part due to the drug, and explains why it is that digitalis is so much more effective in most cases of valvular disease with failing compensation than any other heart stimulant or tonic, for all the others seem to have, and probably do have, but a temporary stimulating effect.

In a brief paper entitled "The Choice of the Various Preparations of Digitalis," published in the THERAPEUTIC GAZETTE for August, 1897, the writer has pointed out the fact that digitalin, digitoxin, and digitalein are the principles of digitalis soluble in alcohol, and that they are also the principles which chiefly stimulate the heart muscle, the digitalin also stimulating the vagus nerves. On the other hand digitonin depresses the vagus nerves and is insoluble in alcohol. It is therefore manifest that when we desire to aid the heart in cases of valvular disease we should use an alcoholic preparation of digitalis in preference to any other pharmaceutical product or even the powdered drug itself, and this may be accomplished by employing the tincture, or better still, a tested fluid extract which is of known and definite strength.

The experiments were carried out as follows: Search was made for a litter of ten pigs in which each pig would be, at the time of starting the experiment, about the same in weight and degree of development, and in good health. Such a litter having been found of the age of two months, each pig was weighed and the lot divided into two batches of five each, one of which was to act as a control experiment, while the other batch was to receive ascending doses of digitalis. Care was taken in making the division that for each pig placed in batch No. 1 another of as nearly as possible the same size was placed in batch No. 2, so that there might be no difference in size between the control pigs and those which were to receive the drug. As far as possible an equal division was made as to sex. The pigs in each batch were then marked by lead tags inserted in their ears, so that in the event of their escaping from one pen to the other no confusion would arise. The two sets were then placed in two pens side by side and provided with separate feeding troughs so constructed as to prevent spilling of the contents as much as possible. Precisely the same manner of feeding was employed for both sets, the food being first prepared in one receptacle and afterward divided into two equal parts, to one of which, that designed for the second batch, was added ascending amounts of Parke, Davis & Co.'s normal liquid digitalis, a fluid extract which is as nearly as possible a standard preparation containing the active ingredients of the drug, since each package of the crude drug is first tested by physiological methods before it is prepared for the market. This is the only test which can be satisfactorily employed to determine the probable physiological activity of a given sample of the drug over and above those commonly resorted to by pharmacists and chemists who estimate the probable value of a given fluid extract or tincture by ascertaining the amount of extractive, which indicates that the crude drug has been properly exhausted. It is not possible at present to make a chemical assay of digitalis.

Before the experiment began the pigs were weighed and were described as follows (January 2, 1897):

CONTROL FIG.		Weight.
No. 1 (boar)	.....	35 lbs.
No. 2 (boar)	.....	36½ lbs.
No. 3 (sow)	.....	39 lbs.
No. 4 (sow)	.....	33 lbs.
No. 5 (boar)	.....	40½ lbs.
Total weight	.....	184 lbs.

## DIGITALIS FIG.

	Weight.
No. 1 (boar).....	37¼ lbs.
No. 2 (boar).....	35¾ lbs.
No. 3 (sow).....	38 lbs.
No. 4 (boar).....	31 lbs.
No. 5 (boar).....	43 lbs.
Total weight.....	184¼ lbs.

The first dose of digitalis was given on January 14, 1897, owing to the delay of the apothecary, who had sent for the particular preparation demanded. The dose was ten minims of the "normal liquid" named, given to the five digitalis pigs night and morning, or approximately two minims to each pig twice a day. The dose of the same preparation for man is from one to three minims a day. On February 14, one month later, the dose was doubled, and on March 14, two months later, tripled (thirty minims). On April 3 it was raised to forty minims, and on April 17 to fifty minims. In other words, each pig received about ten minims twice a day after this time. As the weight of the pig was much less than that of a man this dose was equal to about 60 to 100 minims of the fluid extract a day per pig. This is a very large dose, but produced no ill effects owing to the ascending doses and probable partial immunity.

As early as the middle of March the farmer reported the pigs that were "getting the medicine . . . livelier and bigger than the ones that are not getting it."

On May 2, 1897, about four and a half months after the beginning of the experiment, the pigs were weighed on the same scales and killed by a butcher by an incision across the aorta (death by hemorrhage). The hearts were removed by me and carefully weighed after the cavities had been cleaned of blood and clots by the use of clean water poured through them. The results were as follows:

## CONTROL FIG.

	Weight.	Weight of heart.
No. 1.....	78 lbs.	5 ozs.
No. 2.....	78 lbs.	5 ozs.
No. 3.....	87¼ lbs.	5½ ozs.
No. 4.....	55 lbs.	4 ozs.
No. 5.....	99 lbs.	6¼ ozs.
Total weight.....	397½ lbs.	25¼ ozs.

## DIGITALIS FIG.

	Weight.	Weight of heart.
No. 1.....	82¼ lbs.	5 ozs.
No. 2.....	83 lbs.	5½ ozs.
No. 3.....	86 lbs.	6 ozs.
No. 4.....	70¼ lbs.	5½ ozs.
No. 5.....	95½ lbs.	6¼ ozs.
Total weight.....	417¼ lbs.	28½ ozs.

It will be seen from this record that the total weight of the control pigs is less by about twenty pounds than the digitalis pigs, and that the hearts of the control pigs weighed less by  $3\frac{1}{4}$  ounces than the hearts of the digitalis pigs. It is true that in pigs No. 1 and No. 5 of the digitalis series the hearts weighed the same as the control pigs, but on the other hand it is a fact that in No. 5 the control pig weighed more than the digitalis pig.

While these results, so far as weight of the animals and the hearts are concerned, are not sufficiently in favor of the digitalis to prove simple cardiac hypertrophy under its use, it is interesting to note that the increased activity of the circulation in the digitalis pigs resulted in an increase in general activity during life and greater weight by twenty pounds.

The hearts were now placed in separate jars containing formalin solution and shipped to the Pathological Laboratory of the Jefferson Medical College, to Dr. W. M. L. Coplin, Professor of Pathology, whose microscopical report is appended, and to whom the writer is under great obligations for the careful study which he has made.

## REPORT.

Specimen of pigs' hearts sent to the Laboratory by Professor H. A. Hare.

Ten pigs' hearts preserved in formalin, strength of solution not stated.

Five specimens were in jars marked with Arabic numerals, and five in jars labeled with Roman numerals; those in Arabic, in addition to the number, have upon each label the word "Digitalis," while those numbered in Roman numerals have nothing on the labels but the number.

On macroscopic examination the ventricular wall is very much thicker in the digitalis hearts than in the others; it also cuts with more resistance, and seems uniformly firmer. The increase in the thickness of the left ventricular wall is very much more marked than of the right.

The fixation has not been perfect, and the deeper layers of the muscles have not been penetrated by the formalin. In order to make a microscopic study of the specimens, pieces were taken from near the apex of each ventricle, and all of the specimens treated exactly alike.

The blocks of tissue removed were placed in separate containers and the container numbered, the corresponding number being placed in a note-book, with the number of the heart

and the number of the specimen, so that during the subsequent examination it was not known whether the observer was working with tissue from one or the other heart.

Each piece of tissue was dehydrated in alcohol, cleared in cedar oil, infiltrated with paraffin, sectioned, and cemented to the slide, cleared up, stained with hematoxylin and eosin, dehydrated, cleared in creosote, and mounted in balsam.

Measurements were made by means of the filar micrometer, the rulings having been previously standardized with a stage micrometer for  $\frac{3}{4}$  and  $\frac{1}{8}$  objectives, and a tube length of 160 millimeters.

The tissue was mounted in two pieces so as to secure transverse and longitudinal sections; three sections were mounted from each block, and three measurements made from each section, the mean taken for the record; altogether, 270 measurements were made from each series, with the following results:

Of the hearts from the pigs which had not had digitalis the following results were obtained: No. 1, .1166 millimeter; No. 2, .1125 millimeter; No. 3, .0916 millimeter; No. 4, .0833 millimeter; No. 5, .0791 millimeter.

Digitalis hearts give as an average of all the measurements: No. 1, .1125 millimeter; No. 2, .1166 millimeter; No. 3, .1208 millimeter; No. 4, .1166 millimeter; No. 5, .1208 millimeter.

It is well known that the size of the muscular fiber varies widely; measurements being given as .05 millimeter to .25 millimeter. The size of the muscular fiber is alleged to depend upon the activity of the muscle, the condition of its nutrition, and the condition of the muscle at the time of measurement—that is, whether the fiber measured is relaxed or contracted. It is presumed that under nearly all conditions the measurement is made in the condition of contraction, and particularly is this true of a heart in which the cavities are so readily emptied by bleeding, as occurs in the ordinary method of killing lower animals. Taking into consideration the age of the animal, its general nutrition, the method of killing, and the subsequent contraction of the heart, it is to be inferred that the measurements above given are made under conditions favorable to obtaining the highest measurement.

The highest measurement of the normal heart (.1166 millimeter) is higher than the lowest measurement of a digitalis heart (.1125 millimeter), but the lowest measurement of the normal heart (.0791 millimeter)

is far below the measurement in the heart from the pig which had had digitalis (.1125 millimeter).

Taking the sum of the measurements of the five hearts from animals having had digitalis, and deducting from that the sum of the measurements of the five hearts from animals which had not had digitalis, we find that the difference is .1042, which divided by five, in order to reduce it to the unit of one muscle fiber, gives us a result of .0208 millimeter, which represents the mean increase in size of the heart muscle fiber in the animals which had digitalis.

While this difference, amounting practically to .02 millimeter, strikes us at first as being very small, when we come to remember that it is between one-fifth and one-tenth the diameter of the muscular fiber under ordinary conditions, it practically accounts for the increase in the size of the heart without the necessity of referring that increase to the growth of new muscular fibers.

Thus, if it can be demonstrated—and the above calculation seems to do as much—that there is an increase in the diameter of the muscular fibers amounting to one-tenth, and if under the administration of digitalis the weight of the heart is increased one-tenth, it would then seem probable that the entire increase would be due to an increase in the size of the muscular fibres, rather than to an increase in the number. If, however, heart No. 1 (digitalis) weighs more than the normal, the increase could only be explained by assuming an increase in the number of the muscle fibers.

In conclusion I wish to thank Dr. W. P. Read, assistant in pathology, for valuable aid in conducting this rather tedious and prolonged investigation. Dr. Read infiltrated, sectioned, stained, and mounted the tissue; and working together we duplicated all measurements in order to, as fully as possible, control our results. We have separately conducted the calculations for a mean result in each set of measurements in both series, in order to avoid mathematical error, and to further avoid this danger all vulgar fractions were calculated with a denominator of five figures, and decimal fractions to four figures; the results obtained by both systems were acceptable only when they coincided.

The fact that on macroscopical examination the ventricular wall is much thicker in the digitalis hearts than in the hearts of those animals which received no digitalis, as noted by Professor Coplin, was also remarked

upon by the writer when the pigs were killed. This point seems to be of great importance, and its interest is increased by the additional statement that the muscle cut with more resistance and seemed uniformly firmer. Another point of very great interest is that the increase of the left ventricular wall was far greater than of the right.

In this connection it is of interest to consider for a moment the theory that the pneumogastric nerves, for which digitalis has an especial affinity, are the trophic nerves of the heart, and if this be so it is not hard to understand why digitalis increases the size of the heart muscle. Whether this trophic influence be exercised or not, it is well known that the effects of this drug upon the heart are such that its muscle fiber obtains a greater supply of blood with each cycle by reason of the increased force of the systole, the heightened arterial pressure, and the prolonged and increased diastole.\*

This research would therefore seem to prove that the prolonged use of digitalis is capable of producing cardiac hypertrophy in the normal heart, and if this is the case it is fair to assume that when the drug is given to a man suffering with valvular disease with deficient compensation it must aid materially in inducing compensatory hypertrophy, in addition to any immediate stimulant action which it may exercise in the circulatory apparatus.

#### *PSEUDO-MEMBRANOUS LARYNGITIS.*

BY BURT RUSSELL SHURLY, B.S., M.D.,  
Detroit, Michigan.

In a discussion of pseudo-membranous laryngitis or laryngeal diphtheria it is not necessary to emphasize their histological identity, or to consider in detail the various pathological questions that have agitated the profession from time to time. From a pathological standpoint it is sufficient to recognize that pseudo-membranous laryngitis is in the great majority of cases diphtheria, and can be demonstrated as such by the culture tube.

The etiological factors of membranous croup are numerous. Conditions favoring the growth of the Klebs-Loeffler bacillus are especially prevalent in our large cities. The presence of the bacillus in these cases is so

frequent that we must consider its growth as the direct cause of all cases, unless we have positive bacteriological evidence of its absence. Croup develops more frequently during the fall and winter months, when high winds prevail accompanied by cold and moisture. Poverty and ignorance, with the attending exposure and unhygienic surroundings, subject the children of the lower classes to disturbances of circulation that render them highly susceptible to microbic invasion.

As a complication of measles or scarlet fever the Klebs-Loeffler variety is comparatively rare, though exceedingly fatal. Hypertrophied tonsils, adenoids or other chronic inflammations of the nose or throat increase the susceptibility. Age is an important factor; the frequency of croup increasing from infancy to five years, when it rapidly decreases.

Loose methods of quarantine, although the best possible under the present conditions, are responsible for much indirect infection. Bad drainage and sewerage seem to be factors in its frequent occurrence along the unpaved streets. Laryngeal diphtheria is contagious largely in its own peculiar type; three or four cases of the primary variety often appearing in one family. Five families under my observation developed two severe cases each, making ten intubations with nine recoveries.

The initial symptoms of laryngeal invasion are hoarseness and a characteristic cough. The later symptoms—increasing laryngeal stenosis, the accelerated pulse, and rising temperature—indicate the onset of a graver stage of the disease. The struggle for air becomes gradually worse; cyanosis develops; the blue lips and finger-nails, a clammy skin, rude respiration, hyperpyrexia and semi-stupor complete the clinical picture of a case rapidly approaching a fatal termination. Such is the usual history of neglected cases, asphyxia occurring among children under three years in thirty-six to forty-eight hours. Many cases develop much more slowly, however, continuing for a week or ten days before grave dyspnea develops. Toxic absorption from the larynx is gradual and comparatively feeble.

Laryngeal diphtheria must be diagnosed from bronchopneumonia, acute laryngitis, laryngismus stridulus, and foreign bodies. With a thorough history, a bacteriological examination, inspection of the throat and larynx, and attention to the characteristic sounds of laryngeal obstruction these cases may be differentiated.

\* See article on Digitalis in author's *Text-book of Practical Therapeutics*.

Retro-pharyngeal abscess can be excluded by digital examination. The presence of a tonsillar exudate and attending hoarseness usually marks the onset of the disease, and in children between the ages of one and six years should be considered diphtheria. Ninety per cent. of croup cases without treatment succumb. The result depends largely on the age of the child. From infancy to two years the progress is rapid and bronchopneumonia frequent. Nasal stenosis from any cause, but especially from adenoids, makes the prognosis much more grave. Under the most modern treatment without antitoxin statistics show a mortality of sixty to seventy per cent. In my experience of 121 cases seen in consultation during the past year, ninety of the most severe type were intubated, with a mortality of twenty-six, or 28.9 per cent.

In considering the therapy of laryngeal diphtheria we find no more forcible demonstration of the marvelous results of scientific research than is shown by clinical observations and study of the curative and prophylactic effects of antitoxin. Collective investigation statistics furnish a most convincing argument in its favor. The mortality in children under two years is reduced from sixty per cent. to 33.3 per cent.; many cases of laryngeal stenosis are relieved without operation.

According to the latest opinions of clinicians of the largest experience there is only one safe method of treatment in cases of membranous croup, and that is to consider every case diphtheria until it can be proven something else; meantime administer antitoxin. Treated along this line of therapy the method becomes exceedingly simple. In every case of invasion of the larynx there are two prominent indications that confront us: (1) Prevent extension of the membrane to the bronchi; (2) relieve the laryngeal obstruction. The combination of antitoxin and intubation does the work. New and striking confirmation of their efficacy is presented in every statistical report. Welch shows a reduction in the mortality of intubated cases from 62.4 to 31.6 per cent.

Emetics and the numerous solvents that were formerly relied upon have now only a limited use. Calomel, iron, and the bichloride of mercury are valuable accessories in a large number of cases. One specific with its strikingly beneficial results admits of no substitutes. Exactness, simplicity, and highly satisfactory results are now possible in the

treatment of this disease. The therapeutic measures resorted to in every case should include: Antitoxin 1500 to 2000 units administered as early as possible and repeated within twelve hours if the symptoms do not show marked improvement; 5000 units may be necessary. A liquid diet is of the greatest importance, as much embarrassment of respiration often results from overloading the stomach. Milk administered at frequent intervals and in small quantities, albumen water and beef broth furnish sufficient nourishment. Chipped ice and steam inhalations will relieve the thirst. Calomel should be administered at the onset to unload the bowel, and in children too young to expectorate should be repeated in twenty-four hours, so that the swallowed secretions may be passed by the bowel. Judicious stimulation with whiskey and strychnine should be carried out in all cases, whiskey being of special value in intubated cases to excite a cough when the tube shows a tendency to fill with mucus. Intelligent nursing is an important feature in the treatment of these cases that must not be overlooked. In nine intubated cases under my observation where a trained nurse was employed seven recovered, the two fatal cases occurring from pneumonia, a grave prognosis having been given before the nurses were called.

An ice-collar or iced cloths applied over the larynx have a tendency to modify the rapid growth of the bacilli. Sprays or irrigations of peroxide of hydrogen and lime-water diluted should be used in the throat where the age of the child permits. Turpeth mineral in doses of two to five grains, repeated in fifteen minutes if necessary, is usually a prompt emetic. Its use is now extremely limited, although it has proved very efficient in temporarily relieving asphyxia while awaiting the arrival of an intubationist. The continued use of emetics, however, is decidedly injurious to the patient.

The prophylactic treatment of diphtheria is not given the attention its success deserves. Antitoxin in doses of 250 to 500 units is a valuable aid to the natural powers of resistance. The immunity it confers can be relied upon for at least two weeks, and in many cases is sufficient for a month. Its use in the large children's hospitals of Boston and New York, and the Children's Free Hospital and the Woman's Hospital of Detroit, have thoroughly demonstrated its value as a preventive measure in epidemics.

In neglected cases, and at times in spite

of the most careful treatment, the laryngeal stenosis gradually increases, restlessness and recession of the chest walls is noted, when the propriety of surgical interference should be considered. The judgment that decides this problem under our modern methods of treatment must be based on a wide experience and a thorough knowledge of what antitoxin will do. The choice of surgical measures has been decided by the results of experience, and intubation as a primary operation has entirely superseded tracheotomy. Dilatation and catheterization of the larynx have been abandoned. Since the introduction of antitoxin intubation has fulfilled every requirement as a relief for laryngeal stenosis, and its general adoption by the profession of the old world seems only a question of time.

With the increasing knowledge of the merits of antitoxin and a keener appreciation of its curative effects it seems only rational to predict a still greater decrease in the mortality of croup.

From a study of this subject the following conclusions seem justifiable:

1. Laryngeal diphtheria is particularly contagious in its own peculiar type; therefore immunize all exposed children of croup age.

2. Hoarseness and laryngeal cough following an exudative tonsillitis are sufficient indications for the administration of antitoxin.

3. In measles or scarlet fever the complication of croup should receive prompt treatment.

4. The earlier in the course of the disease antitoxin is given the more favorable the prognosis becomes.

5. Cases intubated in the comatose state just preceding death will show fifty per cent. of recoveries.

The antitoxin used in all of the 121 cases considered in this article was obtained from the Detroit Board of Health, and bore the label of Parke, Davis & Co.'s Biological Department.

#### THE OPERATIVE TREATMENT OF HEMORRHOIDS.

BY GWILYM G. DAVIS,

Surgeon to the St. Joseph, Episcopal, and Orthopedic Hospitals, Philadelphia.

From the amount which is written in the medical journals on this subject one would think that it was thoroughly exhausted. I take it, however, that it is rather an evidence that the professional mind is decidedly at sea as regards the best methods to be pursued.

It is a subject that demands more serious consideration than it often receives. To judge from much that is written one would think that an operation for the cure of hemorrhoids was easy and simple of performance, quick in healing and recovery, and accompanied with little discomfort to the patient and any amount of glory to the surgeon. That this is so of some cases is no doubt true, but not of all. In my opinion the operation is one that demands both skill and great care in its performance, as well as in the after-treatment, otherwise the patient will suffer considerable annoyance and discomfort and the results be more or less disappointing. Two operations—ligature and the clamp and cautery—are usually done. If one was to judge by the number of adherents the clamp and cautery is the more popular. The ligature has, however, among its advocates so many good and true men that it certainly can be considered a perfectly proper and efficient mode of procedure. Recently another plan has been coming into use—that of excision. It is this which I prefer to use when possible.

When the hemorrhoids are limited in number and extent, forming two or three distinct projecting masses, then they can be dealt with effectively by almost any method. The clamp and cautery I dislike principally on account of the insecurity it gives as regards bleeding. My experience has been that after the most careful cauterizing of the stump, when the clamp is released there is often such an amount of bleeding as to require either a reapplication of the cautery or the application of a ligature—usually the latter. In the subsequent manipulation required to cauterize the remaining hemorrhoids the eschar attached to those previously treated is apt to be detached and bleeding again set up. Even after the patient has been put to bed I have known hemorrhage to occur and occasion the attendant considerable trouble and the patient much distress before it was controlled. If narrowed down to a choice my preference would be the ligature. The advocates of the cautery would say that a *proper* method of employing it would obviate the objections stated; to which one might reply that if too much of the submucous tissue is not included in the ligature the occurrence of pain would be avoided. The object desired is to elaborate a perfect technique. A common and annoying occurrence is the presence of feces at the time of operating. A usual mode of preparing a patient for this operation consists in administering a purge, fol-

lowed on the morning of the operation by an enema. Sometimes this is sufficient and sometimes not. It is far better to administer a purge on at least two successive days previously, and then on the day of operation to give an enema of plain soap-suds early in the morning and another just before operating. The patient should be restricted to liquid diet for at least twenty-four hours previously. Even this may not prevent feces from coming down, but it is far more apt to ensure a clean operating field than is a single dose of purgative medicine and one enema. The next thing to do is to stretch well the sphincters. This in itself will sometimes cure hemorrhoids, while if it is omitted the spasmodic contraction of these muscles after the operation will be the cause of considerable pain. Then introduce a speculum and study the diseased area and formulate a plan of attack. Observe if a fissure is present; if so, take care

This procedure is done two, three or four times, as necessary.

The operation is completed by inserting with a curved needle and catgut as many sutures as may be desired to approximate any cut or bleeding surfaces. The sponge is to be removed and a suppository of iodoform and opium inserted, some powdered iodoform dusted on the wounds, cosmoline smeared on the surrounding parts, and a pad of gauze and a T-bandage applied.

In ligating the tissues clamped it is better to do so by several single stitches instead of using one continuous stitch, such as that used by saddlers. When the clamp has been used as often as has been thought desirable, as sometimes occurs, and there still remains a suspicious pile-like area, it has been my practise sometimes to pass a catgut ligature through it and ligate it, so to speak, subcutaneously. This is only resorted to when it

to include and remove it in operating. Introduce a large sponge or piece of gauze through the speculum so as to prevent as far as possible any discharges from coming down. With a hemostatic forceps grasp the apex of a pile and raise it and apply the long, slender-jawed forceps shown in the illustration—made two or three years ago for me by D. W. Kolbe & Son—clamping tightly. With a round sewing needle threaded with catgut pass a stitch through and back again beneath the clamp and tie. Repeat this until the whole amount of tissue included in the clamp is ligated.

It is essential that a round and not a sharp cutting needle be used. The latter of itself will cause annoying bleeding. If the skin has been included in the grasp of the clamp an incision should be made through it with a scissors; the catgut ligature will then lie in it. The portion of the pile above the clamp is then cut away and the latter loosened. If there be any bleeding points they should be caught with forceps and ligated with catgut.

is not desired to excise any more tissue on account of the liability of producing stricture. In extensive cases in which the entire anal mucous membrane is involved I resort to Whitehead's operation of complete excision.

The patient after the operation is kept on liquid diet. The next problem is to have the bowels move without pain to the patient. This is accomplished on the fourth day, or when a desire for a movement is experienced, by introducing a two-way catheter or even a large single catheter and washing away with warm saline or borax solution any accumulated feces. This procedure may be repeated once the next day or day after, and then teaspoonful doses of Epsom salts given until thin, watery movements occur. These will take place without pain or straining, after which the patient is allowed out of bed.

This line of procedure is not given as a perfect solution of all the questions involved, but it is the one that has given me the greatest satisfaction. I can leave the patient,

after the operation, with a sense of security, feeling that neither he nor myself will be incommoded by subsequent hemorrhage and the "passing of tacks," an experience usually complained of if the bowels are allowed to move unaided.

#### ON THE REPAIR OF WILL LOSS.

BY J. MADISON TAYLOR, A.B., M.D.,

Neurologist to the Howard Hospital, etc., etc., Philadelphia.

In the *International Clinics* for July and October I wrote a series of articles on the subject of the disturbances of volition such as are so commonly the sequences of long-continued illnesses and half-invalid states, baffling the best efforts of physicians, and forming the ground in which much future wretchedness may and does grow. It occurs to me that a summary of the points aimed at might prove useful and suggestive to the readers of the THERAPEUTIC GAZETTE. A large proportion of those who apply to the physician for advice have suffered their evil state for months or years, gradually drifting into one or another phase of self-deception and misconstruction, till not only are invalid habits contracted, most difficult of dislodgement, but there comes finally an utter incapacity to honestly relate symptoms or judge of the due importance of one or another item of indisposition, causing the sufferers to unwittingly deceive both themselves and their medical director.

My suggestions are eminently practical (illustrated by typical instances) and divided into: First, such hints as shall help the physician to protect himself against misinterpretation; second, estimation of the grounds of evidence as shall enable him to predicate whether, under the usually complicating circumstances of life and environment, he may expect a cure or only partial relief; third, points of differentiation between how much or how little of benefit may be reasonably expected in each of these most puzzling and complicated cases; and fourth, hints are offered how to proceed in striving for howsoever much is possible of restoration to mental and physical vigor.

It will be obvious, when this outline is contemplated, that satisfactory results can only be accomplished among these folk by thoughtful classification of the special varieties and needs of each case; because this form of disorder is always of slow growth and due to overmuch self-sollicitous and

family attention, much comparison of thoughts and feelings both from these sources and the various physicians honored by their confidence, until at last the product is an exceedingly weird and impressionistic picture of physical and mental disrepair.

One point is common to all such cases—a distortion in the consciousness, a deficiency in normal volition or impulse, amounting to what I call, for want of a better term, "will loss" or perturbation; and upon this single item most of our attention must be focused.

Long protracted ill health produces an almost inevitable misconception of the status of the individual, especially as to his or her actual needs. The springs of action from frequent interferences discharge irregularly, and control influences (normal inhibition, etc.) become palsied and dead. These cases of "will loss" become, oftentimes, exceedingly accomplished critics of medical men, their manners, methods, powers, and limitations, and above all of their peculiarities and weaknesses. Thus the last physician consulted is in a false and perilous position, and woe betide him if he fail to realize his jeopardy! If the patient applies for advice frankly and puts himself, or is put by his family, unreservedly in the hands of the leech selected, all will as a rule go well.

Any sensible, competent medical man who once becomes familiar with the matter and gets the patient fairly in his full control is probably able to arrange a line of procedures; and, if he be resolute and resourceful, can push these to a successful issue. Far otherwise is it where a perpetual distrust befores the already sick consciousness—where suspicion, distrust and conceit induce the sufferer to begin treatment by all sorts of reservations, stipulations for special privileges, and in various ways to assume an attitude of unhelpfulness, advancing weird theories on the "case," and specifying the particular atmosphere in which alone such a one is content to dwell while submitting to repair measures.

Here are all the elements of difficulty and disaster, especially where these reservations include submission to only so much of treatment as is practically unessential, excluding too often those points absolutely imperative. The first measure of relief is a clear understanding of the pathological items; next comes the individual peculiarities; then the family views—including the amount of authority with which they are willing to invest the physician, who should have full control; also the financial status must be defined—

learning how much is possible to be done in the way of furnishing rest, nursing, change of scene, etc.; then comes a clearing away of all old moth-eaten relics of medical misconceptions; and a healthy mental attitude must be induced, at the head of which stands a fair-minded obedience to that mutual agreement which should be defined and entered upon betwixt patient and physician. Then follows a host of needful points, chiefly of a psychological nature, involving moral problems; and finally, a gradual upbuilding of wholesome volition, an acquirement (in which the physician acts as "guide, philosopher, and friend") of healthy views on the duties and privileges of life as it opens up to each one.

### *THE TREATMENT OF THE MALARIAL FEVERS.*

BY CLARENCE J. MANLY, M.D.,  
Louisville, Ky.

The malarial fevers, while all depend upon the same specific cause, occur in several clinical forms, which may be classed in four groups:

1. Intermittent fever, characterized by the paroxysm, which typically consists of the three stages of chill, fever, and sweat; and the intermission, during which the temperature is normal and the patient in comparative comfort.
2. Remittent fever, in which the temperature never reaches normal, consisting of a series of exacerbations and declines.
3. Pernicious fever, with severe symptoms and rapidly fatal end.
4. Malarial cachexia, with anemia and enlarged spleen, due to a chronic infection.

The researches of Laveran, followed by those of Marchiafava and Celli and many other observers, have enabled us to attribute a common origin to all these forms and to diagnose them accurately, by showing that the causative factor, the plasmodium malarie, is always present in the blood of patients affected with malaria, and can there be demonstrated in case of doubtful diagnosis. They have also elevated the treatment of malaria from the domain of empiricism to that of scientific therapeutics, by showing that the specific, quinine, in solution in the blood acts as a direct poison to the malarial organism with which it there comes in contact.

Certain indications are common to all forms of malarial infection. These I shall mention

first, afterwards taking up the special points connected with each type which demand attention.

Cinchona and its products are the specifics for malaria, and of these quinine is the type. It may be administered by the mouth, by rectal injection, in suppository, hypodermically, by intravenous injection.

For administration by the mouth the sulphate of quinine is usually prescribed. In ordinary cases it is best given in the form of pills or capsules to conceal the taste. These should be fresh and easily soluble, so as not to pass into the intestine undissolved, as the alkaline juices there form an insoluble precipitate with quinine, preventing its absorption. It is taken up from the stomach and circulates in the blood as the chloride. Very large doses are apt to irritate the stomach, consequently when a very strong impression is desired it is better to divide the dose and give part by the stomach and part by the rectum or hypodermically. When there is urgent need for an immediate effect it is better to disregard the taste and give in solution, which can be effected by the addition of aromatic sulphuric acid in the proportion of one minim to each grain of the alkaloid. When in solution no vehicle will mask the taste, but if necessary the back of the tongue can be painted with a two-per-cent. solution of cocaine to destroy this sensation.

In some cases, especially with children, the patient is unable to swallow pills or capsules. Here the salt can be given in suspension and the taste modified by some vehicle. Acid is not to be added, as it will form a solution and the taste will not be masked. Licorice and yerba santa are excellent vehicles for use in these cases; for example:

R Quinine sulphate, 16 grains;  
Syrup yerba santa comp., 2 ounces.

M. Sig.: Teaspoonful three to five times a day, for a child of one year.

Chocolate is another vehicle, in which the tannate is often given in the form of confections. Though tasteless, the tannate is of very low alkaloidal strength (22.6 per cent.), hence a large dose is required.

Quinine is readily absorbed from the rectum, and may be given either in enema or in the form of suppository. Ten to thirty grains may be used, dissolved with the aid of acid as above, and given in starch water. Opium may be added to prevent the tenesmus which is unfortunately apt to ensue. Sup-

positories are made in the usual way, with cacao butter as the basis.

Hypodermic injections of quinine are apt to be painful, but the action is prompt and decided, and this means of entrance is particularly valuable in cases of coma, irritable stomach, etc. Injections into the calf of the leg seem to be particularly painful. The point of election is midway between the great trochanter and the tuberosity of the ischium. Probably the best salt for use by this means, when obtainable, is the (unofficial) carbamide hydrochlorate or hydrochlorate of quinine and urea, which dissolves readily in its own weight of water, and is unirritating to the tissues even in concentrated solution. The bisulphate has been recommended, with the addition of tartaric acid (one grain to five of quinine) to the solution to maintain the acid reaction and prevent precipitation in the tissues by the alkaline juices. The hydrochlorate is much used, on account of its solubility. Should all these be obtainable, the sulphate can be utilized in the method recommended by Dr. George Dock, as follows: The solution is made in the strength of ten grains to one fluidrachm, so that a hypodermic syringe will contain from three to five grains. The capacity of the syringe should be accurately known. The salt is mixed with distilled water, adding dilute sulphuric acid drop by drop until the whole is dissolved, and then adding water to make the required quantity. The injections should be made deeply. The resulting pain can be alleviated by hot applications.

The method of intravenous injection devised by Baccelli is indicated in desperate cases, where other avenues fail; and its use under these circumstances has been attended with brilliant results. The solution he recommends is as follows:

- ℞ Quinine hydrochlorate, 15 grains;
- Sodium chloride, 12 grains;
- Distilled water, 2½ fluidrachms.

Having been boiled and filtered, the solution is injected preferably into a vein of the leg as being some distance from the heart, concentrated solutions of quinine being direct local depressants to the heart. The strictest asepsis should be practised.

The enormous doses of quinine which were once given have been shown to be excessive. Binz, by experimentation, showed that in solution of 1:20000 quinine was quickly destructive to organisms similar to the plasmodium malariae, and a dose of five grains will make a solution in the blood of a strength

approximating 1:16000. Clinical experience also has proven that in the milder forms of the infection from fifteen to thirty grains between the paroxysms is sufficient to arrest them. In the pernicious form, however, it must be pushed for its effect. The hypodermic dose should be about one-half that by the mouth, and when used by the rectum the dose should be somewhat more than by the mouth. For children, Rotch gives the dose as half a grain for six months and under, and at the rate of one grain for each year of age over that, up to the adult dose. In some persons even small doses of quinine produce very unpleasant effects, in the shape of eruptions, tinnitus aurium, vertigo, and other symptoms of excessive cinchonism. In some of these cases if quinine can be used in minute doses it will have the same effect as the full doses in individuals without the idiosyncrasy. In other cases some other means must be adopted to combat the infection. Of these, arsenic is valuable in the more chronic cases, but is of comparatively little benefit in acute malaria, a very large dose being required for any effect at all. Methylene blue, in dose of one to four grains, is one of the best substitutes for quinine. Narcotine, two to five grains three times a day, is recommended by Ringer as having marked anti-periodic effects. Certain drugs are useful to combat the unpleasant effects of cinchonism. Morphine, one-sixth of a grain hypodermically, with one one-hundredth of atropine, not only does this, but acts as an adjuvant to the quinine in curing the disease as well. Ergot and the bromides, given with quinine, mitigate the unpleasant effects. A convenient method is to give the quinine dissolved in dilute hydrobromic acid. It is now seldom necessary to resort to these means, as the modern method of smaller dosage has done away with the worst of the effects which used to be so pronounced. All the succedanea of quinine are vastly inferior to it in effectiveness, and should be adopted only in the presence of direct contraindication to that drug. The fear of producing an abortion should not prevent the use of quinine in pregnant women, as it has little or no effect upon the uterus except at term. The malaria, if not checked, would more likely cause abortion than the quinine.

*Intermittent fever* is at once the most common form of malaria and that most amenable to treatment. If seen during a paroxysm the administration of quinine should be delayed,

as it will not abort the attack, but will rather increase the discomfort. A hypodermic of morphine at this time will do much to mitigate the severity of the symptoms; or one-fifth of a grain of pilocarpine hypodermically will have a like effect. If the chill be severe stimulants may be needed, with friction, hot applications, etc. During the fever ice, ice-water and acidulated drinks may be used to allay the thirst, with spongings and the ice-coil if the temperature should become excessive.

It is during and after the sweating stage that the specific treatment is to be carried out, and it should be pushed energetically with a view to warding off, if possible, the next paroxysm. Aside from the discomfort, there are several important reasons why the disease should be promptly checked: (1) The pernicious form is nearly always preceded by one or two attacks of the intermittent variety, and if promptly treated might be aborted; (2) each paroxysm is accompanied by a disintegration of the corpuscles of the blood, causing progressive anemia, and is injurious by the visceral engorgement which also accompanies it; (3) while individual attacks usually yield promptly, there is a great proneness to relapses, and this increases the longer an attack is allowed to run on.

It is usual to begin the treatment with a cholagogue, such as calomel in four quarter-grain doses a half hour apart, followed by a saline. The idea is to restore the function of the liver, deranged by the malarial poison. The catharsis is also supposed to aid in the absorption of the quinine which is to follow. The efficacy of this preparatory treatment is disputed, however, by such eminent and careful observers as Osler and Austin Flint. With the experience of a long series of researches, Flint claims that the use of cathartics not only is of no benefit, but that it actually antagonizes the interruption of the paroxysms. Where constipation exists, however, mild laxatives are indicated.

The quinine may be given either in a single large dose, or in smaller doses, as five grains, repeated several times a day, and should be kept up until the paroxysms are interrupted. After this the patient should be fortified against the "septenary periods" by giving the quinine on the sixth, thirteenth and twentieth days, thus accomplishing a sort of "fractional sterilization" of the blood. If enlarged spleen and anemia persist, as is especially true in long-continued cases, ergot is of benefit, together with tonic measures—iron, arsenic, strychnine, etc.—as follows:

℞ Reduced iron,  
Quinine sulphate, of each 48 grains;  
Arsenous acid, 1 grain;  
Oil black pepper, 15 drops.

Mix. Make pills No. 24. Take one pill after meals for a month or so.

The regular distinct paroxysms may give place to simply a daily fluctuation of heat. This, indicating that the system is still infected, would call for continued active treatment.

As it takes from three to five hours for a dose of quinine by the mouth to attain its full effect, it should be given at least this length of time before the next paroxysm is expected. Otherwise it is best to wait for the next remission.

*Remittent Fever.*—Here the quinine is to be pushed in the remission. The organisms seem to be in a condition of lowered vitality at this time, and the treatment has a more pronounced effect on them; indeed, in some cases it is the only period in which remedies seem to have any effect at all. If the remission is not distinct the thermometer may be used to identify it. The stomach is often quite irritable, preventing treatment *per os*. Here one of the other avenues must be used. If there is bilious vomiting, it should be encouraged by warm water until the stomach is emptied, and then the stomach quieted by abstinence from food and the administration of lime-water, and if necessary opium. The strength must be maintained, giving food and stimulants per enema if necessary. The same septenary precautions and after-treatment by tonics would apply here as in the intermittent form; also the use of sponging, etc., to combat high temperature, and other palliative measures.

In many cases Warburg's tincture seems to have an admirable effect, possibly due in some degree to the combination of aromatics with the quinine. It is especially recommended by Maclean, who declares it to be superior to quinine alone in remittent and pernicious fever; especially so in those varieties characterized by excessive congestion. It should be given in the dose of a half-ounce, undiluted; repeated once, if necessary, after two or three hours.

*Pernicious malaria* differs from the other varieties only in the extreme severity of the symptoms, the great prostration, and the imminent danger of a fatal outcome. These call for prompt and most energetic treatment. Cinchonism must be produced as rapidly as possible, and as the variations in temperature are exceedingly irregular, quinine must be

used at once and pushed at every opportunity till its effect is obtained, large doses being necessary. The stomach can rarely be used, and it is here especially that the method by hypodermic injection and Baccelli's method by intravenous injection serve their most important purpose. The great depression is combated by strychnine and digitalis. In the algid stage reaction can be invited by the use of morphine hypodermically, the application of heat, or brisk rubbing with ice.

The heart and nutrition demand attention. For the former nothing is better than strychnine hypodermically *pro re nata*, in dose of one-thirtieth of a grain. The patient must be sustained chiefly by enemata containing whiskey, peptonized foods, broths, etc.

*Malarial cachexia* is the result upon the system of chronic malarial intoxication, which may manifest itself upon various organs. The line of treatment should be directed toward the relief of these various complicating troubles, together with the persistent use of quinine, iron, and arsenic in various forms.

Change of residence on the part of the patient to some locality where he will not be constantly subjected to reinfection is a *sine qua non* of successful treatment.

#### THE POST-OPERATIVE TREATMENT OF SURGICAL CASES.

---

BY THOS. LEIDY RHODES, M.D.,  
Assistant in the Surgical Clinic, Jefferson Medical College  
Hospital.

(Continued from page 731.)

**Feeding.**—The value of appropriate dieting in bringing about a rapid recovery cannot be overestimated. All surgical injuries, whether of soft structure or of bone, heal more rapidly the better the condition of the blood, and it is therefore indicated that an abundant nourishing diet, properly selected with regard to its ready digestibility, should be given after operations of all grades of severity. It is accordingly highly essential that the attendant should be informed in the proper administration of food, how and when nourishment should be given, as well as have some knowledge of the elementary composition of foods, so that he may have a definite idea of the amount of nourishment required and the food value represented in different aliments, and that he may give them in a manner which will stimulate nutrition in the most advantageous way for the early healing of the wound.

The vague directions of some physicians in ordering a "restricted diet," "soft diet," "house diet," etc., have their counterpart in the lengthy dietary of others who in their zeal to promote a rapid healing by the administration of a liberal and superfluous quantity of food render it possible to overcharge the blood with products of nutrition, and defeat the objects in view by burdening the organs of assimilation. In no part of the after-treatment is a proper knowledge and detailed direction more important for the welfare of the patient, and yet so little appreciated or properly carried out. Necessarily a definite knowledge in this direction can only come from a wide bedside experience and the close observation of individual cases, noting the caprices of the patient's appetite, marking the condition of his tongue and the digestive apparatus, seeing that the ingesta are properly assimilated by frequent examination of the urine and other discharges, and that the needs of the organism are properly supplied. In this brief paper we can only enter into a few of the practical points in feeding that are most essential, and offer a few suggestions which will act as a guide to the physician who has charge of the case.

If the operation was a *mild* one attended with but little shock and loss of blood, but still of sufficient severity and of such a nature as to confine the patient to bed for some days, as in tendon elongation for clubfoot or the opening of a psoas abscess, the diet need only be restricted until the effects of the anesthesia have passed away and the stomach has fully regained its normal condition, which usually occurs in the course of twenty-four hours. The nausea and vomiting will usually have subsided in these cases four or five hours after the operation, and the patient is given several ounces of hot tea or coffee, without sweetening, sipping it from a spoon. If this is retained, he is given two hours later a small glassful of iced milk and Vichy water, or a cup of cocoa, or half an ounce of liquid peptonoids, which is repeated in the course of several hours; or beef tea or beef jelly may be substituted for these. This may be continued at intervals of several hours throughout the night if the patient be wakeful, together with bits of cracked ice or occasional swallows of cold water. If beef tea is given special care should be taken in its preparation so that it will be acceptable to the patient. It is such a valuable and nutritious food that as an article of the sick-room dietary it cannot readily be dispensed

with and is often indicated and very generally used, but the majority of the preparations which the writer has seen and tasted would turn even a healthy stomach. Preparation as follows will yield a savory beef tea: Cut the fat from a pound of lean and juicy beef (preferably from the rump or round), and mince the meat. Put this into a skillet, pour on cold water until the meat is covered, and allow it to soak two hours; then let it simmer on the stove for an hour longer, boil quickly, and strain. The thin layer of fat floating on the top, which makes the food so unpalatable to patients and likewise hard to digest, is removed by dipping pieces of blotting-paper over the surface, until all the grease is absorbed. By seasoning the fluid with salt and pepper to the patient's liking it will usually be taken without trouble and indeed with much relish. None of these liquid foods are given during the night, however, if the patient sleeps. On the following morning he may partake of a light breakfast of soft cooked eggs, toast, and tea; and later, in the absence of fever and gastro-intestinal disturbance, he may resume his accustomed diet.

On the other hand, if the operation has been a *severe* one the dietetic management will be a matter of more serious import. The attending shock, the intractable nausea, the great prostration and a failing heart make the proper administration of stimulating and nourishing food a matter of much concern, and one on which more than on anything else hinges the chances of the ultimate outcome. Proper dieting will then be a most important consideration. This fact has always been recognized by surgeons who have been eminently successful in obtaining satisfactory results in hazardous cases where other operators, less appreciative of the value of such knowledge, have failed. The elder Gross, realizing the benefits extended to his patients from the administration of a suitable dietary, was wont to remark that were he ill he would want a physician "who knew more about food and less about drugs," and there can be no doubt of the suggestive truth of this remark, and the influence which suitable food and nourishment will have in bringing about a quick recovery after serious operations.

For the sake of simplifying the dietetic management in serious cases, we will divide these into two classes, viz.: those in which abdominal section has been performed and the gastro-intestinal tract has been disturbed, as in intestinal anastomosis, excision of the

appendix, and the removal of abdominal growths; and those in which operations of magnitude have been performed in other regions, as in breast extirpation, trephining the skull, and major amputations.

In both these classes of cases the anesthesia will have been continued over a considerable time, and the shock, depression, nausea and vomiting are usually so severe and prolonged that while the administration of nourishment is urgently demanded by the system, it must be carried out carefully and cautiously so as not to aggravate the untoward symptoms.

In the latter class of cases, in which the peritoneal cavity has *not* been invaded, the gastric irritability usually subsides in the course of six or eight hours, and the patient is then allowed to sip from a spoon two ounces of hot tea, without milk or sugar. If this remains on the stomach without causing any further disturbance, he is given in the same manner several ounces of chicken broth or beef broth every two hours until he falls asleep, or throughout the night if he is wakeful. At times, however, the vomiting will be prolonged, especially in susceptible patients, and will not readily yield to the measures instituted to control it. This will further depress the greatly weakened patient and will make the demand for nourishment still more urgent, but as feeding by mouth would only aggravate the gastric irritability and favor egestion, the stomach is given entire physiological rest and the rectum is utilized for feeding purposes. Sufficient aliment will be absorbed from the mucous membrane of the rectum and sigmoid flexure, after the injection of a properly prepared nutrient enema, to supply nourishment to the tissues and sustain the strength until the vomiting has ceased, even though this continue over several days, and in intractable nausea is the only safe method of alimentation. In employing this method the attendant must be assured that the rectum is cleansed of all mucus and feces. If a copious enema of soap and warm water was given just prior to the operation in anticipation of later complications, the rectum will be empty and rectal feeding may be carried out at once; but if such is not the case the lower bowel must be flushed with a soap and water injection before the food enema is given. This preliminary douching will not only cleanse the mucous surface but will stimulate the circulation in the parts and favor absorption. If much mucus comes away with the enema and there is much rectal irritation it is well to add boric acid

to the injection. The nutrient enema must be given immediately after the rectum is cleansed. In preparing this only such materials should be selected as will be rapidly and completely absorbed. Slowly absorbable foods act as foreign bodies and will soon be expelled. Starches and fats are not taken up at all, so cannot be employed. Food-stuffs that are predigested, composed principally of albuminous substances, are best adapted for this use, and milk, eggs, and meat juice, all properly pancreatized, form the basis of the many formulæ which are used by surgeons in rectal alimentation. In the Jefferson Hospital coffee is usually combined with the pancreatized milk, two ounces of each, with the addition of an ounce of whiskey. Professor Keen prefers the simpler formula consisting of beef extract and whiskey, of each a half ounce, and pancreatized milk, three and a half ounces. A method which is somewhat more complicated but which has proved eminently satisfactory in the writer's hands is as follows: To three ounces of fresh milk is added an ounce of cold water in a clean vessel, and the pancreatizing powder, consisting of pancreatic extract 0.5 grain and sodium bicarbonate 15 grains, is added while stirring, together with the whites of two eggs. This is placed in warm water, at a temperature of 95° F., for half an hour. A slightly bitter taste will signify that fermentation has proceeded far enough; a little salt is added to favor absorption, also a half ounce of good whiskey, and the whole is ready for injection. The water is added to dilute the milk, as milk in too concentrated a form will act as a foreign body, and strong whiskey is *not permissible*, as it coagulates the casein in the milk. The yolks of the eggs are discarded as they are commingled with so much fat, which is absorbed only by the villi in the small intestine.

Attention to the minutest details in administering the enema will be necessary to get the full benefit of the injection. The patient is turned on his left side if his condition permits, and his hips are raised on a pillow. A flexible rubber (Nélaton) catheter is lubricated with vaselin and is passed into the bowel (remembering that the direction of the lower inch points toward the umbilicus), for a distance of eight or ten inches, which will bring the eye of the catheter into the sigmoid flexure. In children a No. 12 caliber will be sufficiently large, but in adults a No. 20 should be used. Special care must be exercised on inserting the tube if the

patient be subject to hemorrhoids, so that undue irritation is not caused. The injection is preferably given by means of an ordinary large glass or hard rubber syringe—the amount injected can be seen in the former, but the latter is less fragile. The syringe should hold about two ounces and should be thoroughly clean. The patient is told not to strain as the fluid is slowly forced up into the bowel by successive syringefuls until the whole enema has been injected. The advantages of placing the enema high up in the bowel are that it is retained better, it is brought in contact with a more extensive mucous membrane surface, and a physiological reason exists which was pointed out by Thompson: The superior hemorrhoidal veins form the commencement of the inferior mesenteric vein, which also receives the blood from the sigmoid flexure, while the vessels in the lower third of the rectum terminate in the internal iliac vein. Consequently what is absorbed from the lower third of the rectum passes into the internal iliac and vena cava without going to the liver, while that which is absorbed higher up is carried through the branches of the portal vein directly to the liver, and it is here that the final digestion and assimilation of the proteids take place. On withdrawing the tube, which is done rather quickly, a compress of gauze or cotton, which is in readiness, is placed between the buttocks and pressure exerted either with the hands or a T-binder for twenty minutes, the patient's position remaining undisturbed during this time, after which he may be arranged more comfortably.

These enemata are repeated at intervals of six hours, until the stomach is finally settled and again in condition to receive food, which may be on the second, or possibly on the third or fourth, day. As soon as the nausea is controlled, stomach feeding is resumed with sips of hot tea.

Rectal alimentation is often indicated after extensive operations on the larynx, jaws, and tongue, but it can usually be replaced at the end of a day or two by feeding the patient by means of a soft catheter passed through the nose, providing reasons exist which make it unwise to allow feeding by mouth. The catheter is soaked in warm water, lubricated with vaselin, and passed gently through the lower nasal fossa down into the esophagus. Milk, beef tea, broths, and punches are used as foods in these cases, and before they are poured into the funnel attached to the free end of the catheter or accessory tube, it

must be made certain that the patient is breathing freely and that the end of the catheter has not entered the trachea. This method is repeated every four hours until the patient may again take nourishment by mouth.

On the *second* day, if there has been no necessity for nasal or rectal feeding, a liquid diet of milk and broths is maintained, administered by mouth in small quantities every two hours, in order to coax back to a normal condition the depressed and enfeebled powers of digestion. If there is very marked lack of nerve energy it is well to begin in the early hours of the second day with several ounces of black coffee, if the patient's stomach will bear it, and particularly if he has not had the invigorating influence of a night's sleep. This should be given hot and sweetened to his liking, and should be taken from a cup through a glass tube bent at a right angle near the middle, so that the nurse can see how much the patient is swallowing, his head being slightly raised by the nurse placing her hand beneath the pillow and raising both together. If the patient is extremely weak the cup is raised so that the fluid flows through the tube into his mouth without effort. Owing to the enfeebled digestive functions, milk will be the staple article of diet on the second day, but many patients will assert, from previous experience, that they cannot endure the taste of milk, and that the peptonized form, which would throw the least amount of work on the stomach, is peculiarly intolerable to them. The various modifications, such as Pasteurized milk or modified milk, which disguise the taste but retain the nourishing qualities, may then be used. Albuminized milk, largely used by Professor Keen, and usually very acceptable to the patients, is made by putting the whites of three eggs and three ounces of lime-water into a corked bottle, which is shaken for five minutes; a half pint of milk is added, the bottle is again shaken five minutes, and sugar and sherry wine are added to suit the taste, except the patient be a child, when the wine is omitted unless especially indicated. Kumiss (milk prepared by simultaneous lactic acid and alcoholic fermentation) is also usually an acceptable form for administration, and has the advantage of helping to allay the tendency to gastric irritability. Even raw milk, with a little perseverance on the part of the nurse, and making use of the many methods of altering its taste, will be effectually retained by starting with small doses, and rapidly increasing these until

a sufficient quantity is ingested. In disguising its taste, coffee, caramel or ginger are useful, or chocolate, cocoa or common salt may be tried. If alcohol is indicated it may be combined advantageously in the form of weak punches, with a dash of nutmeg, or as an egg-nog, with whiskey, sherry, or rum. None of these added agents affect the nutritive value of the milk in any way.

Milk in any of these forms is given in small quantities at first, and frequently repeated—several ounces every two hours—and the patient is fed slowly so that no large curds will form in the stomach. When he is convinced of his ability to retain it, the quantity may be increased according to the stomach's tolerance. The milk on hand must be kept cold and covered, and a simple refrigerator for the sick-room may be improvised by wrapping a large piece of ice in a piece of flannel and placing it in a pan or pail. Wine whey and junket (milk curdled with rennet) will also be found agreeable to the patient, as well as chicken, veal, or mutton broth, made like beef tea, and administered in like manner and quantity. After each feeding the patient's mouth is rinsed with pure water or borax water to prevent the fermentation of that which lingers between the teeth and which might interfere with digestion.

On the *third* day a more substantial diet may be inaugurated by the addition of farinaceous foods and the light meats of fowl. A return to this more substantial food is often marked by a flagging appetite and an indisposition of the patient to partake of anything except that which is brought to him at regular intervals and in fluid form. The still marked depression, however, demands the stimulation and nourishment from heavier food, and it is then that the value of precise instruction from the surgeon, and of tact on the part of the nurse, particularly assert themselves.

Vaguely indicating that "soft diet" should now be given generally means the administration of raw milk and eggs in indefinite quantity, and vegetables and puddings and breads in a promiscuous way that may not agree with the patient and still more sicken and depress him. Hence it will be a matter of great importance, not only to determine just what articles of food are to be administered, but that all the niceties in serving them be employed, in order to stimulate the patient's appetite. Small quantities should be given at a time at appointed intervals, and in courses, even though these be very limited,

instead of placing everything before him at once, and should be served on attractive china and with spotless linen, using different receptacles for food than those used for medicines to avoid the association of ideas. The food must not in any way show signs of defective cooking, and must be given properly minced and diluted, neither in too concentrated a form nor too weak, as bulky and highly concentrated foods require too much effort to masticate and to digest, and diluting the milk and gruels too much, or making the beef tea and broths too weak, tires the patient in swallowing, and his head sinks on the pillow before sufficient nourishment is obtained. The nurse will also allow a proper interval to elapse after removing the vessels employed for the discharges before offering nourishment, and will make use of the many dainty ideas of the sick-room regimen that will suggest themselves to her, and which will contribute much to the patient's appetite.

The farinaceous foods which will be found most serviceable at this stage and which will usually be acceptable to patients are: arrow-root boiled and flavored with lemon peel, hot oatmeal gruel from which the hulls have been removed, corn-starch mixed with milk, and farina made up with milk and eggs. These may be served with the three daily meals which are again introduced, but are preferably used with the morning and evening feedings, the heavier diet of meat and dry breads being reserved for the midday meal. Cornmeal gruel and flour, and mashed rice and cream, both served hot, will also be of service, but are slightly harder to digest and not usually relished as much by fastidious patients. With these may be served tea or coffee, and toast, either dry or boiled with milk, and soft cooked eggs, shirred, poached, or boiled. The midday meal will consist principally of nitrogenous food, clam juice heated, minced light meat of a tender chicken, a boned squab or reedbird, or the soft parts of oysters in season, with Graham bread and milk. Punches and broths are given between times and before the retiring hour, and permissible liquids during the night as desired. This dietary will be repeated on the following day, with the addition of a baked sweet apple or baked banana, or stewed prunes or pears, and a baked potato with the ends cut off to allow the water and steam to escape. On the *fifth* day the red meats of beef and mutton may be substituted for the fowl and squab, provided there is no marked rise in temperature or visceral congestion; and from

this day on the diet need no longer be restricted.

Should inflammation set in, with a decided pyrexia, the foregoing diet will be modified to some extent by withholding the red meats and supporting the patient's strength with the articles of food mentioned that are easily assimilated, and that can be given in ample quantity. Local inflammation with constitutional symptoms means increased tissue waste and increased expenditure of force in the evolution of heat, which must be replenished by an adequate amount of nutritious food. But as in inflammatory conditions the appetite and digestive power are likewise lessened, it would be injudicious to overtax these functions by the administration of the heavier foods. The demand will be more in the line of the lighter and easily digestible materials, with a plentiful supply of demulcent drinks, particularly in the form of punches and egg-nogs. Should the inflammatory process go on to a chronic stage and be attended with the formation of pus, the diet need no longer be restricted, and a regimen consisting largely of fresh green vegetables and fresh fruits is indicated, as these will be serviceable for their antiscorbutic and laxative properties. Fats, which are likewise indicated in suppurative processes when administration by mouth is not admissible in the form of olive and cod-liver oil, can be supplied by daily inunctions of cacao butter or goose grease.

If the operation was an *abdominal section*, for appendicitis, intestinal anastomosis, or the removal of morbid growths, the dietetic management during the first few days will be markedly different from that set forth above. Invasion of the peritoneal cavity, particularly if attended with much manipulation of the viscera, for the time being interferes with the normal peristaltic action of the bowels and partially paralyzes their functions, hence the food that is given must be of a very easily digestible character, so that the dangers of indigestion, malfermentation and flatulent distention will be avoided.

From close observation in these cases it has been found that milk, and the articles of diet in which it is incorporated, is the chief offending factor in causing gaseous distention, and its use during the earlier days after an abdominal section has now been entirely abandoned. In its place have been substituted foods that are less liable to cause these untoward symptoms, as tea and coffee, liquid peptonoids or nutrient wine (which consists

of a high percentage of beef peptones dissolved in good wine), broths, beef extracts, and water ices.

After the operation, if there is marked depression and nausea demanding stimulation and nourishment, the patient is given an enema of coffee two ounces, whiskey one ounce, and beef extract a half ounce, which is repeated every four hours until the stomach is quieted and able to receive food. As in the case of stomach feeding, milk is proscribed in the enemata. The demand for these nutrient enemata usually does not extend over the first twenty-four hours, and they can generally be replaced on the morning of the second day by the regular methods of feeding. If the enemata are given after operations in which a Mikulicz drain or a copious vaginal tamponade has been used, it must be borne in mind that the pressure from these may seriously interfere with absorption. The nausea being but slight, or responding to treatment in the course of several hours after operation, the patient is given sips of hot water in drachm doses at intervals of half an hour until every vestige of gastric irritation has disappeared. Two ounces of hot tea or coffee, without sweetening, is then administered slowly, which quantity is repeated every two hours; or in lieu of this may be given two drachms of nutrient wine or liquid peptonoids, properly diluted. Small quantities of dry champagne will often be grateful as well as nourishing. These may be alternated and continued at two-hour intervals during the night if the patient be wakeful or extremely weak. On the following morning the day is begun with a small cupful of coffee or tea, and the diet from thenceforth may be set down in a general way as follows:

*Second day.*—7 A.M., small cupful of coffee or tea without sweetening; 8 A.M., small cupful of beef broth or chicken broth; 10 A.M., nutrient wine or liquid peptonoids; 12 M., meat juice, half an ounce; 2 P.M., nutrient wine or liquid peptonoids; 4 P.M., beef extract or beef broth; 6 P.M., coffee or tea, and meat juice; 8 P.M., nutrient wine or peptonoids; 10 P.M., chicken broth.

*Third day.*—7 A.M., coffee or tea, poached egg on toast; 10 A.M., chicken or mutton broth, nutrient wine; 12 M., dry toast, broths, peptonoids, coffee or tea; 2 P.M., gelatin, kumiss; 4 P.M., nutrient wine, water ices; 6 P.M., dry toast, shirred egg, tea or coffee; 9 P.M., chicken broth or beef broth.

*Fourth and fifth days.*—7 A.M., coffee or tea,

soft boiled, shirred, or poached egg, oatmeal gruel (boiled twice), toast; 10 A.M., broths, nutrient wine or peptonoids; 12 M., light meats of fowl, dry toast or Graham bread, calf's-foot jelly, rice, tea or coffee; 2 P.M., nutrient wine or peptonoids; 4 P.M., kumiss, gelatin, broths; 6 P.M., soft parts of oysters, cream crackers, nutrient wine, gelatin or calf's-foot jelly; 9 P.M., chicken or beef broth.

*Sixth and seventh days.*—7 A.M., soft cooked eggs, oatmeal gruel, toast, Graham bread, coffee, tea or cocoa; 10 A.M., cup of mulled wine, broths, nutrient wine; 12 M., small piece of beefsteak or chop, baked potato, thin slice of wheaten or Graham bread, tea or coffee; 4 P.M., chicken broth with rice, corn-starch, or farina; 6 P.M., soft parts of raw oysters, toasted Graham bread, wine jelly, tea; 9 P.M., broths and nutrient wine.

After the first week, in the absence of sepsis, fever, and gastro-intestinal disturbances, there is no harm in allowing the patient the full diet of animal and vegetable foods to which he is normally accustomed.

After gastrostomy, nourishment is administered through a rubber tube in the fistulous tract, leading into the stomach, the tube being either fixed in the opening, as in Witzel's method, or removable, as in the more recent plan devised by E. Senn. In the latter method the patient's strength will have been maintained by rectal alimentation for forty-eight or seventy-two hours prior to making the opening in the stomach wall, which usually comprises a second stage of the operation. The food that is introduced through the tube into the stomach will consist of those articles included in the dietary of the first and second days after abdominal sections; with the later addition of milk in various forms when the viscus has become firmly adherent to the abdominal wound and no harm can result from malfermentation. The liquids in ample quantity are poured into a funnel attached to the free end of the tube every three hours, and while the feeding is in progress the patient is asked to masticate pieces of solid food to satisfy in part the sensation of hunger. Feeding by this method will sustain and prolong life many days, and in a case operated upon by Professor Keen during the writer's term of service as interne in Jefferson Hospital the patient gained weight and lived in comparative comfort for many months.

### TREPHINING AS A MEANS OF RELIEF IN CASES OF RESPIRATORY DIFFICULTY FOLLOWING CEREBRAL LESIONS.

One of the most hopeless conditions which the general practitioner is called upon to face is that in which the subject of an apoplectic seizure begins to suffer from greater and greater respiratory difficulty until it is evident that if something is not soon done for his relief death must speedily ensue. By apoplexy we mean that condition in which there has been a rupture of a blood-vessel somewhere in the skull cavity. As a rule the physician finding himself in such a plight can do little else than stand by and wait till death ensues, although if the patient be very plethoric it is certainly a fact that free bleeding from a vein in the arm will often give great relief and save, or at least prolong, life. Similar symptoms also arise from other cerebral injuries and lesions. Various measures have been suggested for the treatment of this state, many of them depending upon an erroneous idea of its cause, and others so radical in character as to be startling in their very suggestion. Perhaps one of the most

radical of these was that of Victor Horsley, namely, compression or even ligation of the carotid artery of the side of the brain in which the "artery of cerebral hemorrhage" had ruptured. The various changes in posture which have been suggested are none of them adequate to meet the condition, except in so far as they equalize the circulation and prevent cerebral congestion, or stasis, by preventing any constriction of the neck by the collar or by faulty position of the head. If the hemorrhage has taken place some hours before and there is reason to believe that it has ceased, and yet the respiration seems about to fail, great benefit may accrue from resorting to Laborde's rhythmic traction of the tongue or even the ordinary methods of artificial respiration. These and other directions will be familiar to those subscribers of the GAZETTE who have read the valuable suggestions of Byrom Bramwell, which were published in the November issue for this year in the department devoted to Progress.

The chief object of this editorial is, however, the calling of attention to the recently made suggestion that in a large proportion of cases the respiratory death from apoplexy results from pressure directly or indirectly exercised upon the most sensitive of all nervous centers, namely, that governing respiration. That failure of respiration is the most common cause of death in many injuries to the cranial contents is proved by experience, for the heart as a rule continues beating for some minutes after breathing ceases. This fact is particularly emphasized by Dr. J. Lacey Firth in the *Bristol Medico-Chirurgical Review*, where in the course of an article he quotes a case of meningeal hemorrhage, recorded by Hutchinson, in which the pulse continued five minutes after the respiration ceased; and in another case of Fagge's in which the pressure of a cerebral abscess caused arrest of breathing with a continuance of the pulse-beat for ten minutes while artificial respiration was maintained. In another case the pulse lasted for thirty-five minutes. To quote more directly from Smith's article, he proceeds to state that Mr. Horsley mentions four cases he has met with, all of them being cases of tumor of the brain. In three of these the respiration ceased suddenly as the operation of trephining was being proceeded with, and in these the operation was quickly completed and tension relieved, when the power to breathe naturally returned. Mr. Horsley writes: "Cases of cerebral hemor-

rhage, of cerebral tumor, and of depressed fracture, as well as cases of sudden and violent concussion, especially when applied in the occipital region, die from failure of respiration, and not, as is so often surmized, from failure of the heart." Mr. Horsley also maintains that in those cases in which persons have been described as suddenly falling down dead, in consequence of violent blows on the head, *e.g.*, from a fist or cricket ball, or from an explosion, the fatal ending has resulted from respiratory paralysis, and might in some of them have been avoided by performing artificial respiration.

Macewen refers to two cases of respiratory paralysis. In one of these the heart continued to beat regularly for twenty-four hours after natural respiration had ceased. The source of pressure was a cerebral abscess. Mr. Jalland, of York, relates a case in which the breathing ceased when trephining was being proceeded with, and was not restored until pus was evacuated from a cerebral abscess. Another abscess case, where the heart continued beating for six hours, is reported from the Liverpool Royal Infirmary. Drs. Sawkins and Vallack, of Sydney, give notes of six cases of respiratory paralysis, all ultimately fatal. Two of their cases were of basal meningitis, with internal hydrocephalus; the other four respectively of intraventricular hemorrhage, cerebral hydatids, cerebellar tumor, and malignant tumor of the base of the skull; the length of time during which the heart continued to beat varied from ten minutes to two hours.

Firth finally records a case of his own in which he resorted to trephining for the relief of the pressure, which, though indirectly exercised on the respiratory center, seemed to be about to cause immediate death.

This patient was a male child, two years of age, and was admitted to the hospital at 1 P.M., soon after a fall upon the head from a first-floor window. There was no scalp wound, but each parietal and temporal region was greatly swollen. The symmetrical swellings gave the head a very curious appearance. They were soft and boggy to palpation. The patient was very incompletely conscious and very pallid. He lay for the most part still and quiet, but movements of each limb were made in response to cutaneous irritation. The pupils were equal and rather wide. They acted sluggishly to light. Vomiting occurred two or three times in the first two hours after admission. There was no hemorrhage from the ears. The pulse was 120; the respi-

ration normal. Two hours later the patient responded less to stimuli. The left pupil was perhaps a shade larger than the right. The right arm and leg were moved fairly briskly on stimulation, but the left hardly at all. Soon after 6 P.M.—*i.e.*, rather over five hours after admission—respiration suddenly ceased, and cyanosis became marked. Artificial respiration was begun at once, as the heart was beating regularly and yielding a fair radial pulse. He had not an opportunity of seeing the patient between three and half-past nine. At ten o'clock—*i.e.*, three and a half hours after the cessation of respiration—he removed, by trephining, two discs of bone from the right side of the skull. The first disc was over the anterior branch of the middle meningeal artery. The dura here seemed very tense, and was incised, but the brain did not bulge out. He attributed this to the small size of the aperture and the viscosity of the brain. The posterior disc was divided vertically by a fissured fracture of the skull. Through the uppermost exposed part of the fissured fracture a flake or two of brain substance had exuded. No removable source of pressure was discovered through either aperture.

The heart at the end of the operation was acting as strongly as at the beginning. Artificial respiration was kept up as well as possible during the operation, and for two hours longer. The artificial respiration was continued until the heart's action ceased, which was six hours and ten minutes after the onset of the paralysis of the respiratory center. During the last hours of life transient systolic cardiac bruits were frequently heard.

The reason he trephined on the right side rather than on the left was that in his earlier observations there was a much weaker response of the left limbs to stimuli than of the right.

The post-mortem examination showed that if the other side had been chosen the pressure might have been much more effectually relieved.

We have already called attention in a complimentary manner, in an article upon Chloroform in the February issue of the GAZETTE for this year, to a valuable monograph on the Physiology and Pathology of the Cerebral Circulation by Mr. Leonard Hill, and from this and other researches it becomes evident that free trephining is to be practised in a certain number of seemingly hopeless cases of apoplexy or other cause of increased intracranial pressure. When the damage to

the cranial contents is so great as to necessarily result in death no good can come of the operation and no harm. In other instances it may save life, and it should always be tried in cases in which respiration ceases and the practise of artificial respiration fails to give relief. During the performance of the operation, and after it until all hope is lost, artificial respiration by Sylvester's method should be constantly practised.

---

*THE RELATIVE VALUE OF THE TABLET  
TRITURATE IN ITS VARIOUS  
FORMS AND IN COMPAR-  
ISON WITH LIQUID  
PREPARATIONS.*

---

The introduction of the triturate for the administration of medicines was a distinct advance in pharmacy because it better prepared the medicament by minute subdivision for solution and absorption. It was also a gain in therapeutics for these reasons, but even those advantages did not render them very popular with the profession. It was not until the discovery was made that triturates could be readily formed into tablets that they became popular preparations, since in this form physicians could readily carry and prescribe remedies which hitherto had been difficult to handle and to measure in an accurate manner at the bedside of the patient. As a result we now have before us, or rather behind us, the accumulated evidence of the value of this manner of administering remedies, and it is important to consider whether the physician and his patient gain as much when the latter receives drugs in tablet triturate form as he does when the older method of dispensing tinctures or fluid extracts was resorted to. Our attention has often been arrested by this question, and has been recently called to it once again by a letter from a subscriber to the GAZETTE, in which he asks whether tablet triturates, compressed or uncompressed, are reliable, and if they maintain their medicinal properties. The reply to this question seems to rest upon the character of the drug with which the triturate is made. If, as in the case of *cimicifuga*, which is supposed to depend upon a volatile substance for its usefulness, the drug parts with its chief virtue on prolonged exposure, it goes without saying that the triturate is not to be used, and that a well prepared and well preserved fluid extract is preferable. On the

other hand the permanent drugs, such as many of the mineral substances used in medicine, can be kept indefinitely in tablet form and yield as good results as ever, as can also many of the medicaments derived from the vegetable kingdom.

The very extraordinary demand for these preparations would seem to indicate that they possess a value far above that due to their mere convenience in dispensing, and seems to answer the question of our correspondent in the affirmative. He also asks for a comparison between the reliability of the average tablet and fluid extract and tincture. The latter preparations certainly deteriorate by long keeping, particularly that most valuable class of products known as fluid extracts, and it may be laid down as a rule, we think, that if the physician will renew the contents of his medicine case containing tablet triturates as often, or half as often, as he usually renews the contents of the bottles holding fluid extracts he need have no cause to fear that his therapeutic results will suffer by the use of the tablet. There are of course greater opportunities for well concealed dishonesty in the preparation of tablets than of liquid preparations, and each tablet if carelessly made may not contain an identical quantity of the drug, but this is to be avoided by the patronage of a reliable manufacturer. Most medicaments had better be prescribed in the ordinary tablet form than in the compressed form, which cannot be as soluble. Further than this, many of the drugs which are naturally slow of solution in the alimentary tract are the very ones which require enormous pressure in the machines in order to make their individual particles cohere, and thereby are practically like bullets when swallowed, often passing through the bowel with only their surface dissolved.

Our correspondent questions the usefulness of tablets containing more than one ingredient, and we agree with him, for it is better to give several tablets representing several single drugs, if we seek a combined effect, than one tablet in which the various quantities may not be those desired or which may contain an ingredient entirely useless for the case in hand.

In the case of ergot and other drugs whose active principles doubtfully represent the fluid extract, it is probably best to use the liquid form, but in the case of the greater number of drugs the tablet, if well made, may be relied upon.

*THE RESULTS OF NEPHRORRHAPHY.*

The fixation of a movable kidney in its proper position by suture has long been recognized as a comparatively safe operation. A statistical study of reported cases, particularly that published by Guyon, seems to show conclusively that the mortality is low, that the technique is comparatively easy, that the direct and indirect results are excellent. The direct results are those connected with the relief of kidney pain and congestion and particularly of attacks of kidney colic due to flexion or twist of the ureter. The remote results are those relating to the gastro-intestinal canal, since it has been shown beyond doubt that a movable kidney may so drag upon the duodenum or the colon, or so press upon other viscera, that great suffering and ultimate irreparable pathological changes may be produced. Guyon's statistics show that there is a comparatively large percentage of recurrences, but that this percentage is less when the operation is so conducted that the kidney capsule is stripped and torn up and the sutures are so applied that the kidney substance is brought in direct apposition with the tissues lying behind it.

There has been lacking in most of the published tables a careful analysis of the cases. It is notorious that the tendency of the profession is to rush into print only with successful cases. Hence conclusions derived from a study of the collection of such published cases are necessarily not to be depended upon.

Wolff reviews in the *Deutsche Zeitschrift für Chirurgie*, 46 bd., 1897, a report on twenty cases of wandering kidney operated on by Rose in the last thirteen years. The method of operation was in general that commonly employed; the lumbar incision was made, extending from above the lower two ribs, downward to the crest of the ilium, and exposing Pettit's triangle. The latissimus dorsi muscle was drawn aside or cut through and the lateral border of the sacro-lumbar muscles was exposed and drawn inward if it was broad. The dissection was then carried down to the quadratus lumborum, the oblique insertion of which into the crest of the ilium enables it to be recognized. Pettit's triangle was incised along the border of the quadriceps. The deep wound was as long as the loin of the patient, the upper extremity reaching to the lower border of the twelfth rib, the lower to the crest of the ilium. All

vessels were ligated as cut; with care the lumbar nerve, which runs obliquely across the wound, may be avoided. When the loin is short and the wound small it is sometimes difficult to find the kidney. When it was clearly seen the fatty capsule was torn open with the finger on the convex border, as was also the fibrous capsule. These structures are separated outward and inward. The kidney was then fixed so that its upper pole lay beneath the twelfth rib. This was accomplished by two or three strong catgut threads, which were passed through the kidney substance, including a mass about the size of the finger. The external wound was closed above and below and the middle part was drained. The bandage was changed every day for the first ten days, since some urine leaked out through the needle punctures of the kidney. This change must be made with the patient in the dorsal position, his body being supported by two properly placed bandaging stools. It is important that he should not be turned on his side, since it is always possible that the catgut threads may tear. The patient remains in bed in the dorsal position for five full weeks. The detailed history of the twenty cases follow. In one, because of tubercular disease, the affected kidney was afterward extirpated. In the remaining nineteen nephrorrhaphy was practised twenty-one times. One patient died six days after operation of exhaustion following vomiting, due to great dilatation of the stomach and duodenum. Of the eighteen patients who recovered the wound healed kindly in fifteen; twice there was suppuration causing a long lasting fever. In six cases curetting was necessary before healing took place. In three cases subacute nephritis developed immediately after operation, accompanied by fever; it, however, proved transitory.

Wolff holds that these statistics prove that suture of the kidney is absolutely devoid of danger. Three instances of acute nephritis, one death and several cases of septicemia scarcely seem to prove this contention. As to the lasting result, in two cases the kidney was found fixed in its proper position fourteen years after operation. In the third case the kidney was found to be in its proper position three years after operation. It is noted incidentally that this patient suffered from a slight hernia, requiring the use of a bandage. In one case which required celiotomy three months after the operation because of ileus, the kidney was found properly placed. In

another case fifteen months after operation examination under narcosis showed both kidneys in proper position. In the majority of the other cases the cure was found to be apparently permanent as far as the position of the kidneys was concerned, but the percentage of these cases that required subsequent laparotomy or subsequent examination under anesthesia is astonishing, and inevitably leads to the conclusion that they still continued to suffer from symptoms for the relief of which they sought the surgeon. Moreover, it is worthy of note that even under ether a healthy kidney properly placed cannot be felt in the vast majority of cases, hence the proof as to the kidney maintaining its position would be at best negative. Since it is implied that the kidneys were felt by abdominal palpation it would seem that they were not normally placed at the time of this examination. The influence of scar tissue on the kidney seemed to be *nil*, in so far as urine examinations were conclusive.

Wolff acknowledges that even though the fixation of the kidney can be assured the relief of symptoms is not so certain. The symptoms may be classified under the headings: Pain, gastro-intestinal disturbances, and neurasthenia. The pain and dyspepsia he states can be absolutely relieved by fixation. Hysterical symptoms are, however, more obstinate. He states that the affection is absolutely curative in all simple cases of wandering kidney; and that even when this is associated with hysteria, partly through its psychical effect it powerfully influences this condition for the better, and even complicated cases recover from the kidney pain, and that other forms of derangement are then put in the best condition to be benefited by appropriate therapeutic measures.

## Reports on Therapeutic Progress

---

### *THE COLD-AIR TREATMENT OF TYPHOID FEVER.*

J. MURRAY-GIBBES writes on this topic in the *Australian Medical Gazette* of April 24, 1897. He begins by telling us that the subject matter of his paper comes under the head of artificial aerotherapeutics, or, to use a shorter word, aerotherapy. The success which has attended the treatment of typhoid fever by means of cold baths caused him to consider whether we could not attain a like, or even a more successful, result by means less cumbersome than that of placing the patient in

a succession of cold baths. Having this idea in view he addressed a letter to Mr. W. W. Crawford, of Sydney, an eminent refrigerating engineer, asking whether he could suggest for use in hospitals a better system for lowering the temperature of fever patients than that of a succession of cold baths; the temperature to be reduced from, say, 103° F. to 100° or 101° F.

In reply, Mr. Crawford wrote to the effect that there was nothing to prevent the fever wards in hospitals being fitted up in such manner as to permit of the reduction of temperature of any compartment down to as low as 5° F., or its maintenance at any figure between that and the temperature of the external air by the mere turning of a tap, with the necessary machinery upon the grounds, the cost of which would be within the means of a small hospital to meet. Such have usually a steam boiler, probably in connection with the pump. It would be only needful to lay down a small freezing machine, and connect it with the fever ward—which would have to be insulated—by means of pipes, through which chloride of calcium brine circulates, abstracting both moisture and heat from the room, a tap regulating the flow. The machine is simple, and, in addition to the service indicated, it would make ice for the use of the hospital. It could have attachments by flexible tubing for local applications of cold. In the case of ice only one temperature—viz., 32° F.—can be obtained, but with brine circulation any temperature within the range of the machine, either above or below freezing point, may be reached. Expense puts ether out of court. Drawings, etc., could be forwarded, so as to give the hospital authorities full particulars, for which no professional charge would be made by him.

The advantages of the cold-air treatment of fever are the following:

No handling of the patient is necessary.

He will lie on a tube mattress, and be covered by another, through which tubes will flow a cooling mixture, when required to lower the temperature. There is no doubt that experience will prove that this should be a continuous current, so that the temperature of the body can be prevented from rising above a certain degree.

Experience has taught that the cold treatment of typhoid, to be useful, must be carried out "systematically and with vigor," and that "patients endured this repeated withdrawal of heat without experiencing any bad effects." Riegel proved that placing ice-bags on the

chest and abdomen was less debilitating than cold baths, and the cold-air treatment will be found even less so.

The shock to nervous persons of being placed in a cold bath is avoided.

Attached to the cold water tube will be another, which can convey hot water from a hot water source, so that warm water can at first flow through the tubular mattress, and then, by means of taps, the temperature of the water can be gradually lowered to the required degree. As to the degree of coldness of the freezing mixture, experience will have to prove this. Leube, in 1871, laid patients on large pillows containing a freezing mixture of ice and salt of the temperature of about 14° F.

The method of treatment the writer proposes has great advantages over previous ones, in that we can have any temperature we wish "down to so low as 5° F., and its maintenance at any figure between that and the temperature of the external air by the mere turning of a tap." Besides this we can also, by turning another tap, have hot water to pass through the same tubes when necessary in the treatment of any disease.

We can keep a patient for any length of time surrounded by a cold atmosphere, continually abstracting heat, and so preventing him from rising to a dangerous temperature, and that without disturbing him. Cold water tubes can be placed on any part of body where necessary, as in disease of the chest.

Dr. Barr, in 1891, advocated "prolonged immersion in a tank bath" from six to thirty-one days, and pass all discharges into the bath. The present treatment has advantages over this, while the effect is the same, without any of its obvious disadvantages.

We are told that "constancy of temperature depends upon the power which the organism possesses of so controlling the production or loss, or both, that the normal temperature shall not fluctuate in any direction; that in fever this power of control is so impaired or weakened as to make it inadequate for its purpose, consequently the organism loses its power of keeping itself at a normal temperature. Also that "the true danger in typhoid fever consists in the deleterious influence of a high temperature on the tissues. Nearly fifty per cent. of the deaths are due to the direct influence of an elevated temperature, and in the remainder the same influence has a share in producing the complications, or in bringing about the fatal results; so, if we could guard our pa-

tients against the deleterious influence of excessive animal heat, typhoid fever would no longer belong among the specially dangerous diseases."

Liebermeister wrote: "It is as a matter of course entirely immaterial in what way the abstraction of heat is accomplished, provided that a sufficient amount of caloric is actually withdrawn from the body. On the whole, those means will be found preferable which achieve the desired result with the least inconvenience to the patient."

This being his opinion, an opinion all must concur with, there can be no doubt that the cold air treatment proposed will keep down the high temperature of typhoid, and so greatly lessen the death-rate, and can be carried out without inconveniencing the patient in the least.

As the temperature of typhoid patients is generally higher during the night than during the day, the cold-air treatment can be easier carried out, owing to the nursing staff being less during that time, and assistance not easily to be obtained.

The simple turning of a tap cannot be compared with the trouble entailed on the hospital staff in providing a cold bath. In fact, one nurse could attend to a dozen patients with less trouble than to one under the old treatment.

In other complaints the freezing air treatment must prove invaluable, such as sunstroke, and local congestions and inflammations of the chest, etc. Tube pads of various shapes could be made to fit different parts of the body for conveying hot or cold water.

#### UREA AS A DIURETIC.

KLEMPERER (*Berl. Klin. Wchnschr.*, 1896), in an address on the treatment of hepatic cirrhosis, strongly recommends urea as a diuretic. He advises that recent ascites should be treated by means of diuretics and not by tapping, the former being in his opinion a more efficient and lasting method. He records at length two cases of recent liver cirrhosis with ascites which he treated with urea. In both cases the urine rose rapidly, the ascites disappeared, and the result was as satisfactory as can be in such cases. He has also used urea in the uric acid diathesis, stone in the kidney, and uric acid gravel, following the example of Rosenfield (*Centralbl. für Klin. Med.*, Bonn, 1895, s. 28). It dissolves up uric acid freely, and Klemperer found it superior to piperazin and lysidin in

these cases. He gives it up to 150 and 300 grains daily, and there are never any unpleasant symptoms caused by its use. Klemperer is of opinion that, being as it were the natural diuretic, its action is very much more favorable when the kidneys are intact than when they are diseased.

Returning to the subject (*Deutsche Med. Wchnschr.*, Leipzig, 1896, No. 47) after further experience, he still advises its use in ascites and dropsy when not of renal origin. In forty-two cases of stone in the kidney he has found that it is an excellent solvent for uric acid. He gives it simply dissolved in water or in the following combination:

- R Urea,
- Sodium bicarbonate,
- Calcium carbonate, of each 1 ounce.

S.: Half a teaspoonful four or five times daily.

It may also be given in gouty subjects with lumbar pains, when both its solvent action on urates and its diuretic effects do good.

Kohn (*Ztschr. für Heilk.*, Berlin, 1896, bd. xvii, s. 395) has not been able to form so high an opinion of the value of urea. He attended to Klemperer's advice only to give it in cases where the kidneys are healthy. He treated in all ten cases—four of hepatic cirrhosis with ascites, two of pleurisy with effusion, one of pericarditis with effusion, one of tubercular ascites, one of ascites from carcinoma, and one of ascites from cardiac disease—giving daily 75 to 375 grains. In each case the daily amount of urine and its specific gravity were carefully ascertained, and a comparison of the effects of urea and of other diuretics, such as diuretin, digitalis, calomel, and sodium salicylate, was made on the same patient. Kohn found that its action as a diuretic is uncertain, and that where it acts it does so by stimulating the secreting mechanism of the kidney. It has no unpleasant effects. In three of the above mentioned cases there was a marked increase of the urine, but in the others it failed to act; while digitalis, diuretin, calomel, and sodium salicylate all increased the urine more decidedly.

Bettmann (*Berl. Klin. Wchnschr.*, 1896, No. 49) has also tested Klemperer's results clinically. He treated twelve cases—three of liver cirrhosis with ascites, four of pleurisy with effusion, and five of other serous exudations—but in none were the results more than very moderate; 150 to 300 grains of urea was given daily in water, and the results are tabulated. The rise of urine in some cases—as slight, in others it was completely absent,

and in the former it was not enduring. In most of the cases up to six ounces of urea altogether, and in one up to eighteen ounces, were given without causing any unpleasant symptoms in the patients.

Von Noorden ("Real. Encyclop. der Gesamten Heilkunde," 1897, art. "Herzklappenfehler") states that in cases of general cardiac dropsy he has used urea in daily amounts of 90 to 150 grains with excellent results as regards an increase of diuresis.—*Edinburgh Medical Journal*, July, 1897.

#### CARBOLIC ACID GANGRENE.

CZERNY (*Münch. Med. Woch.*, April 20, 1897) observed that whereas some twenty-five years ago there were numerous records of carbolic acid intoxication, yet even in that period the occurrence of gangrene was rarely reported. After referring to some recorded cases, Czerny observes that hardly a semester passes in his clinic without a case of carbolic acid gangrene presenting itself, and he warns his students against the use of watery solutions of this agent. He gives details of three cases recently admitted to his clinic. In all the cases the carbolic acid solution was applied to a wound of the finger. Gangrene supervened, and amputation became necessary. This gangrene is of the dry kind. The anesthetic action of carbolic acid induces the patient to leave the dressing on. The part first becomes grayish-white and eventually black, without any sensation of pain. Circulatory disturbances caused by firm bandaging, inflammation, or a severe injury predispose to it. The above named patients were in robust health, and the injuries were not such as to induce gangrene by themselves. In two of the cases a three-per-cent. solution of carbolic acid was applied, but it was kept on for several days. The duration of the application is more important than the concentration. The author concludes that since with any solution of carbolic acid gangrene may under certain circumstances develop, this agent should be altogether avoided as a dressing, and other antiseptic solution used.—*British Medical Journal*, May 22, 1897.

#### IMMUNIZATION WITH ANTITOXIN.

In the *Archives of Pediatrics* for June, 1897, SHURLY concludes an interesting practical paper on this subject by saying that in private practise the use of the 250-unit dose has, so far as he has been able to observe,

been entirely satisfactory, no patients immunized having developed the disease.

If, then, present observations prove correct, we have a valuable artificial aid to the natural powers of resistance, that can be called into requisition at any time to combat the growth and increase of the diphtheria bacilli.

The following conclusions seem justifiable from his studies:

1. Previous prophylactic medicinal measures have been almost entirely successful.
2. As an attack of diphtheria immunizes the subject for a comparatively brief period only, nothing more can be expected of the antidiphtheritic serum.
3. Immunity is immediate.
4. Fresh serum can be generally relied upon to immunize for thirteen days. The writer's experience is based on the exclusive use of Parke, Davis & Co.'s antidiphtheritic serum.
5. No case of serious kidney disturbance, abscesses or eruption was observed.
6. Serum should be omitted in grave cases of chronic disease.
7. Other acute or chronic diseases are not affected by the serum.
8. The ordinary hypodermic syringe can be used for immunization.
9. The immunizing dose is followed by only a slight reaction.

#### *DIPHTHERIA ANTITOXIN.*

HENRY R. SLACK, Ph.M., M.D., La Grange, Ga., expresses (*Atlanta Medical and Surgical Journal*, November, 1897) a high opinion of antitoxin as a preventive and curative agent in the treatment of diphtheria. His own experience in private practise bears out fully the favorable reports made to the American Pediatric Society by its special committee, and the clinical cases recited by him testify to the prompt and powerful action exerted by antitoxin on both the local and constitutional symptoms of the disease. Dr. Slack concludes that the antidiphtheritic serum should be administered freely and promptly, as the loss of twenty-four hours may mean the sacrifice of a life. He recommends doses of from 1000 to 2000 units, according to the severity of the case, to be repeated in twenty-four hours if improvement is not manifest. A third dose may be given with perfect safety. Dr. Slack urges the use of the most concentrated strength of an absolutely reliable preparation. In his own cases he used diphtheria antitoxin of both foreign

and domestic manufacture. He prefers that prepared by Parke, Davis & Co. for two reasons: (1) it is put up in hermetically sealed, large-necked, glass bulbs; (2) it can be obtained fresher, thus increasing its reliability; while its entire freedom from fatalities, casualties or complications of any kind, its great concentration, and the promptness with which its curative powers are manifested, add to its usefulness.

#### *THYROID TREATMENT AS A MEANS OF CONSOLIDATION IN FRACTURE.*

GABRIEL GAUTHIER (*Lyon Médical*, June 27 and July 11) has been led by the remarkable effect of thyroid medication in cases of disordered nutrition of osseous tissue (myxedema, rickets, etc.) to try the same treatment in cases of retarded consolidation of fractures. Hanau and Steinlein (Frankfort Congress, 1895) had observed that in thyroidectomized dogs in which experimental fractures were made repair was notably delayed, and callus was formed in less amount than in healthy animals, and they threw out the suggestion that "ingestion of thyroid gland might be used by surgeons to promote the formation of callus." Gauthier gives his experience of the mode of treatment in two cases:

1. A strong, healthy country girl, aged fifteen, broke her left leg (*sic*) in the lower third. The fracture was simple, with over-riding of the fragments, which were easily reduced. The limb was put up in plaster of Paris. Union did not take place, in spite of the administration of phosphate of lime, rubbing of the ends of the fragments, etc. When 110 days had elapsed without consolidation taking place Gauthier prepared from the thyroids of young sheep a glycerinated juice, a teaspoonful of which represented one gramme (about fifteen grains) of thyroid substance. Of this the patient took from six to ten teaspoonfuls a day. During the first two or three days she complained of intense headache, flushing of the face, giddiness, and a feeling of suffocation, but a fortnight after the commencement of the treatment the fracture was consolidated, and a month later she could walk about as well as ever. Careful palpation failed to reveal any abnormality in the thyroid gland. The total amount of thyroid substance taken was 120 grammes.

2. A healthy man, aged forty-eight, suffered a fracture of the radius. The limb

was put up in plaster. After three months there was no consolidation. Thyroid treatment was begun, and continued for between three and four weeks, the total amount of active thyroid substance taken being about 160 grammes. Consolidation was then established. In this case, too, the thyroid gland was, as far as could be made out, perfectly normal.

Gauthier, while admitting that two cases are insufficient to prove the value of the treatment, thinks the results in the cases which he records suggestive and encouraging. He adds that whenever thyroid treatment is employed the practitioner will do well, whenever possible, to extract the thyroid himself instead of leaving it to the butcher to do so. Young sheep should be chosen for the purpose. That animal has two thyroids; hence two incisions should be made, one on each side of the trachea. If a median incision is made, especially in a very young animal, the operator is likely to take the thymus instead of the thyroid.

---

*TENDENCY TO BENDING OF THE BONES  
IN CRETINS UNDER THYROID  
TREATMENT.*

In the London *Lancet* of October 2, 1897, T. TELFORD SMITH writes of this interesting question. He believes that one of the most marked among the many other signs of development produced in cretins during the administration of thyroid preparations is the rapid increase of growth in stature which takes place—an effect which is all the more striking when we remember that in these cases growth is almost at a standstill previously to treatment. The boy, notes of whose case are published herewith, grew four and a quarter inches in ten months under thyroid treatment, and his brother grew four inches in less than a year under similar treatment. As a point in the practical treatment of these cases the writer has found that during thyroid treatment this rapid growth of the skeleton leads to a softened condition of the bones, resulting in a yielding and bending of those which have to bear weight; and as cretins under treatment become much more active and inclined to run about, this tendency to bending has to be guarded against. The girl, aged seventeen and three-quarter years, shows this increased bending of the legs very well. She has now been continuously under thyroid treatment for two and a quarter years, taking one five-grain tabloid daily with her

dinner, and during that period she has grown seven and a half inches (from three feet six inches to four feet one and a half inches). During the period of two years previous to treatment she had only grown an inch (from three feet five inches to three feet six inches). For the last few months she has been kept as far as possible at rest, so as to prevent to some degree this bending of the legs. The bending takes place most markedly in the tibia and fibula, the increased size of the ends of these bones at the ankle and knee being very noticeable. Several photographs of cretins before and after thyroid treatment exhibited by Dr. W. R. Parker, of Kendal, and Dr. John Thomson, of Edinburgh, at the meeting of the British Medical Association at Carlisle, showed this increased bending of the legs very clearly, and the condition was remarked upon and discussed, Mr. Victor Horsley showing in this connection slides to illustrate rickets produced in rabbits by Hoffmeister, and in sheep and goats by von Eisenburg, by removal of the thyroid gland.

While in rickets, however produced, there is perverted and delayed ossification resulting in a softening and bending of the bones, under thyroid treatment in cretinism there is rapid resumption of growth in the skeleton, leading to softening, which is most marked in the long bones and at the epiphyses. Cretins under thyroid treatment should, therefore, be watched for any commencing bending of the bones of the legs, and if such appears the child should for a time be hindered from walking or the legs supported by light splints. As an additional means of assisting the rapid bone and other growth the diet should be generous, and the child should get plenty of sunlight and open air. The administration of cod-liver oil would probably prove beneficial at the same time.

---

*THE OBJECTIONS TO CONDENSED MILK  
AS AN INFANT FOOD.*

It is self-evident that the best standard by which an infant's diet can be judged is the infant's normal food—breast milk. It is not alleged by any one that breast milk is always of exactly the same composition, or that it can be exactly duplicated by any artificial food, or that the stomach of the average child has no power of adapting itself to variations in food. But the composition of average breast milk is well known, and any food which varies widely from its proportions, with very little other evidence against it, must be condemned.

If we know that a given food contains but one-eighth the amount of fat and one-third the amount of proteid found in normal breast milk, we can reach but one conclusion regarding it—that food is not suitable for continuous use. Yet these are the proportions of a one-in-twelve dilution of condensed milk. If made twice that strength, the solution contains but one-fourth the proper amount of fat, but at the same time an excess of sugar, the greater part being cane-sugar. As a matter of fact, but few infants will digest condensed milk in a one-in-six dilution. It is rarely given in actual practise in a dilution of less than one in twelve. The objections to condensed milk as an article of infant diet were pointed out very clearly by Dr. Kerley in a paper recently read before the Pediatric Section of the American Medical Association.

No rational physician can believe that a food of such strength can form a proper diet for continuous use in any but the youngest infants. If further evidence were needed, the clinical experience of men who see large numbers of children is available. So far as we know no careful observer of large experience advocates the use of condensed milk alone, because children do not thrive on it. It is quite true that there are exceptions to this as to most rules, but it is folly to base one's practise upon a few exceptions rather than the rule. Dr. Holt with his large experience says that he has as yet never seen a child reared exclusively on condensed milk who did not show, on careful examination, more or less evidence of rickets. Dr. Rotch is equally positive in his statements.

The number of children over four months of age fed exclusively on condensed milk who show no sign of rickets or malnutrition is extremely rare. They are frequently fat, to be sure, but they commonly present striking examples of "fat rickets." As a rule they well fulfil Dr. Kerley's description of them as an "ill conditioned class of children, with their starved muscular and nervous systems, and catarrhal tendencies, who fall an easy prey to bronchopneumonia in winter and to the gastro-intestinal diseases in the summer, and to the infectious diseases during the entire year." As regards well nourished children who have been reared exclusively on condensed milk, Dr. Kerley aptly remarks that "we hear of more than we see."

The chief objection to condensed milk as an infant food is the fact that there is a slight deficiency of proteids and an excessive and almost fatal deficiency of fat.

If condensed milk is an improper food for infants, is it so irreparably bad that it cannot be changed or fortified so as to render it a desirable food? We would say that it cannot be made a desirable food; it may be made permissible. In many cases it is the only available food, and in some cases the most desirable that can be obtained. While granting this, we do not in the slightest degree advise its use when a better food can be secured. It is certainly a fact that the practitioner is sometimes obliged to use it. This occasionally occurs through obstinate persistency on the part of parents, but more commonly among the extreme poor, who cannot afford a more expensive food.

As the chief objections to condensed milk as an infant food are its deficiency in fats and proteids, two changes must be made to render it suitable for use; fat and proteid must be added. As the absence of fat is the greatest defect of the two, it must receive chief attention. This deficiency may be corrected by the addition of cream—an impossibility among the very poor. If cream is not available we may resort to cod-liver oil as suggested by Dr. Kerley. It is an excellent substitute and must be regarded as a food rather than a medicine, and must be given continuously, though the daily amount need not be large. The device of using a meat broth for securing the proteid, as suggested by Dr. Kerley, is an excellent one. As an occasional substitute for the broth, egg albumen may be utilized to supply the necessary nitrogen. The white of an egg may be thoroughly beaten up with the water with which the condensed milk is diluted. The chief objection to this plan is the difficulty of determining the proper proportions to be employed.

By thus modifying condensed milk a child may frequently be carried with fair success to the ninth month. His chances, however, of reaching that age without rickets will be far better with fresh cow's milk.

If the doctor who is wedded to the exclusive use of condensed milk would not make his fresh milk mixtures four to six times as strong as his condensed milk mixture he would be much better satisfied with fresh milk.

In deciding upon the value of a given food, the physician should not fix his attention upon the present so closely as to entirely forget the future. He should consider the remote as well as the immediate effects of the diet. His office is not alone to tide

over a few months and keep a baby quiet at any hazard, but to lay the foundation for strong and vigorous childhood. He will fail to accomplish this if he prescribes a food lacking in its essential elements, though the child may for a few months seem to digest it more readily.—Editorial in *Pædiatrics* for August, 1897.

#### THE DANGERS OF ARTIFICIAL RESPIRATION.

The most obvious thing to do, remarks a writer in the London *Lancet* of August 28, 1897, when a patient fails to take air into his lungs while he is under the influence of an anesthetic is to adopt some form of artificial respiration. In most cases, he says, the treatment is the correct one, but it must not be assumed that in every case in which the breathing stops artificial respiration is the first act to be performed. It is not free from danger; in more than one instance it has led to fracture of the ribs owing to some excited assistant pressing too vigorously upon degenerated bones. The writer refers to numerous cases in which foreign bodies have become engaged in the air passages, and have been discovered only after futile efforts at artificial respiration had been abandoned. Not infrequently, the writer continues, when abdominal section has to be performed to relieve intestinal obstruction there is a fatal tendency for the stercoraceous vomiting, which is so likely to occur during the operation, to result in matter being sucked back into the larynx. This is the great peril of the anesthesia in such cases, and every instance of death under it is a warning.

The following case, which came under observation of Mr. Cholmeley, of Wolverhampton, is cited by the writer as an illustration of this point: It appears that a man, aged fifty-eight years, exhausted by disease, was to be operated upon to relieve obstruction, caused, as was found at the necropsy, by an annular carcinomatous growth constricting the intestines at the ileocæcal valve. The general condition of the patient was very bad, and the operation had to be delayed by the patient's refusal to give his consent, so that at the time he was given the anesthetic his state was a grave one. He took the ether well. What degree of anesthesia was obtained was not mentioned. In ten minutes, the abdomen being opened, and the surgeon being engaged in handling the intestines to discover where the constriction was, the patient began

to vomit. He became livid and a gurgling sound was heard in his trachea. Artificial respiration was resorted to for a short time without improving the man's condition, and then tracheotomy was rapidly performed. A quantity of stercoraceous vomitus issued from the tracheal tube, and although the artificial respiration was kept up the man died.

There can be no doubt, the writer continues, that in cases where it is certain that vomitus has entered the lungs, the first thing to do, as was done in the present case, is to perform tracheotomy and draw out with some pump all the fluid that can be got from the air passages. Artificial respiration, when done by pressing upon the ribs and moving the arms, can only force the stercoraceous vomitus into the finer bronchi and effectually cut off any chance of the patient's recovery. It has been suggested that preliminary washing out of the stomach lessens the risk of vomiting, but it is not at present certain how far this can be relied on as a safeguard, since as the stomach is emptied a renewed regurgitation from the intestines is apt to occur. It seems probable that the inevitable manipulation of the intestines induces the reversed peristalsis which culminates in vomiting. Were this danger considered imminent it might justify a preliminary opening of the trachea and plugging above the tracheotomy tube, so as to effectually shut it off from the pharyngeal space. Whether such a procedure would increase too much the peril of the case experience alone can decide.—*New York Medical Journal*, Sept. 25, 1897.

#### SERUM TREATMENT OF LEPROSY.

Dr. JUAN DE DIOS CARRASQUILLA has reprinted communications made to the National Academy of Medicine of Bogota, Colombia, on the serum treatment of leprosy, and a report by Dr. Pablo Garcia Medina, the secretary of the National Academy of Medicine at Colombia, on Dr. Carrasquilla's experiments. It is evident from the account which Dr. Carrasquilla gives of his experiments that he is familiar with the technique necessary to carry through treatment of this kind, and considering the important results which he has obtained, it is satisfactory to find that they are vouched for by the secretary of the National Academy of Medicine.

When a leper is bled the serum which is obtained from the blood is stated to vary according to the lesions in the patients. In those who are severely affected, and who are

in a bad condition, the serum is milky, sometimes of a greenish color, and has a repulsive odor. If this serum is injected into a horse the animal, immediately after the injection, shows signs of suffering. If a leper is chosen who is not depressed in health, the serum is yellow, limpid, and odorless. This serum injected into a horse produces no morbid phenomena. A young, healthy, vigorous horse is chosen, and the method practised at the Pasteur Institute is followed. A minimum dose of fifteen cubic centimeters produces no reaction; a maximum dose of 150 cubic centimeters produces a violent reaction. Dr. Carrasquilla usually injects fifteen cubic centimeters in small animals, thirty in animals of middle size, and sixty in large animals. He repeats the injection every ten days, and ten days after the third injection the serum is taken, rigorous antiseptic conditions being practised.

It is first ascertained that no toxic reaction is produced by the injection into a rabbit or guinea-pig in a dose of one cubic centimeter per kilogramme of the weight of the animal. A first injection of one cubic centimeter of the horse's serum is then given to a leper, and the dose is gradually increased in the following injections. Usually there is no reaction until after the third or fourth injection. The normal reaction is characterized by a feeling of cold and rigors, which takes place from two to six hours after the injection, and which usually lasts for two hours. There is, at the same time, thirst, malaise, anxiety, headache, and coldness of the extremities. There is often a second or hot stage, whilst the feeling of cold and shivering continues. The pulse reaches 110 to 120 per minute, the temperature generally 38° to 39° C., and rarely as high as 40° or 41° C. Then perspiration follows and the reaction ends. The serum given by the stomach in doses carried as high as five cubic centimeters produced analogous symptoms, but only one experiment had been made at the date of the report.

With the establishment of the reaction from the serum the leprous lesions, it is stated, undergo remarkable changes. In a case of nerve leprosy, which is described in some detail, the result was decolorization of the pigmented spots, return of sensation to anesthetic patches, and general improvement of the health. In a case of marked tubercular leprosy, during the first week of treatment there was abundant desquamation from the surfaces of the tubercles and absorption

of the swelling. The leprous ulcerations began to suppurate freely, and to cicatrize with extraordinary rapidity; and ulcers, which previously were deprived of sensation, became sensitive. Tubercular ulcers and tubercles in the ears and nose disappeared, and the nose resumed its nasal shape. A similar healing process was established in the mucous membranes.

Similar results are described in other patients, and the secretary of the Academy states that the same process of healing took place in all the patients treated, which up to the time he wrote numbered about one hundred.

It is evident that we have here statements of great importance and gravity, and they are vouched for in a manner which makes it impossible for them to be neglected. It is clear that it is the duty of those who have large numbers of lepers under their charge to undertake the control of Dr. Carrasquilla's investigations.—*British Medical Journal*, Aug. 14, 1897.

[Still more recent trials of such serum in leprosy do not give encouraging results.—Ed.]

#### THE ADDRESS IN THE SECTION OF PHARMACOLOGY AND THERAPEUTICS.

Professor LEECH's address at Montreal is an admirable example of the interest and even charm with which a graceful touch and a well balanced judgment can invest a subject usually considered dull. Although he cannot refrain from the temptation to give a retrospect of his theme during the last sixty years, he enriches its bald facts with a wealth of illustrative detail which renders them palatable, and so adds greatly to their instructiveness. These sixty years have done even more for therapeutics than for other branches of medicine, for they have based it upon a new science—that of pharmacology. Before the method of experimental inquiry was applied to the action of drugs, the current views were always uncertain and often ludicrous. It is true that Pereira, the Linnæus of materia medica, was far nearer the truth than his fellows; but while giving him every credit for his great powers of observation, we cannot but feel that many of his correct opinions were only clever guesses. With the growth of the new science, systematic guessing has come to an end; in fact, the action of many new remedies can be approximately stated before they are tried or even manufactured. A certain wise empiricism is necessary to the

advance of science, but even this is governed by laws and kept within well defined boundaries.

Professor Leech lays appropriate stress on the strides in therapeutics which have resulted from a recognition of the relation between chemical constitution and medicinal action. This relation was to some extent realized by Paracelsus, but his views, being carried to excess by his followers, retarded instead of advanced the progress of the healing art. Not until the second quarter of this century was any attempt made at the scientific correlation of the facts observed and their establishment upon an experimental basis. Traube's confirmation and extension of Withering's clinical observations upon digitalis form an excellent example of this, and many others may readily be called to mind. A further step has been the introduction of synthetic compounds into practical therapeutics, partly as substitutes for drugs already in use, and partly as entirely new remedies. It is true that this has not been a wholly unmixed advantage, for of making many specifics there is no end, and the market is well-nigh flooded with what a distinguished surgeon was wont to call "those filthy coal-tar products." Still, many of them have come to stay, and Professor Leech wisely suggests that as our knowledge progresses we may be able to assign to each its proper and individual niche in the therapeutic temple.

But all other advances appear insignificant when compared with the introduction into practical medicine of products of the animal body such as gland extracts and antitoxic serums. The empirical use of the former, mainly as aphrodisiacs, is recorded from time immemorial; one of them is said to have driven Lucretius to madness, while learned disquisitions as to their employment and the terrible effects of an overdose will be found in the works of the Portuguese physicians, Abarbanel and Amatus Lusitanus. Brown-Sequard's unfortunate essay in opotherapy will also be fresh in the minds of all, and it is well known that many savages eat the brains of their slaughtered foes in order to acquire their cunning, and their hearts to acquire their courage. The futility of these efforts offers a suggestive contrast to the brilliant results which have followed the first use of the thyroid gland on scientific grounds. No less notable and, indeed, of even wider applicability, are the effects of antitoxic serum, effects which were predicted by scientific

reasoning before the introduction of the remedies.

Standing as we do on the verge of a new era in treatment, it would be rash indeed to attempt to predict the future of therapeutics. Professor Leech wisely refrains from the endeavor, but contents himself with, on the one hand, protesting, albeit mildly, against the hazardous generalizations of those who have been carried away by the new ideas; and on the other pleading for a more careful and complete study of the action of drugs both customary and recent. He justly emphasizes Schmiedeberg's view, that the first study must be the action of drugs upon undifferentiated protoplasm, the knowledge of which will form its sole accurate basis when complete. We must confess, however, that we cannot follow Professor Leech in regarding "catalysis" as an explanation of the action of chemical substances upon protoplasm. As a matter of fact, the example he gives is not one of catalytic action at all, as manganese dioxide is converted into the chloride in the process of manufacturing chlorine. Furthermore, McLeod has shown that in the preparation of oxygen from potassium chlorate with the aid of manganese dioxide, although the latter is unchanged at the conclusion of the process, it forms a succession of compounds during its continuance. Here we have a glimpse of the true nature of catalysis, a series of changes ending in the reproduction of the original substance, over which they have passed like a wave. We have emphasized this point because it seems to us that the future of all physiology, and therefore alike pathology and pharmacology, must depend upon the wider knowledge which we are bound to gain regarding catalysis, from which we can pass to the question of ferment action and the ultimate problem of all, the properties of protoplasm, or, in other words, the nature of life itself.

Reverting to the special subject of Professor Leech's address, it must be admitted that the limitations of opotherapy, or treatment by animal juices and extracts, are already becoming apparent. The unqualified success of the thyroid gland in the treatment of myxedema has not been followed by any commensurate results from the use of the pituitary in acromegaly, of the suprarenal in Addison's disease, or of bone-marrow in pernicious anemia. The fact that the administrations of these extracts have in some cases been usefully extended to affections not obviously connected with the glands em-

ployed—as, for instance, thyroid extract to psoriasis—tend to obscure rather than elucidate the whole subject. Serum therapeutics would seem to touch a wider horizon, for theoretically it should be possible to antagonize the poison of every disease known to be produced by a micro-organism. Nevertheless, this is not always the case, even with the limited number of affections already investigated. Thus, for instance, in tetanus it appears that a lethal dose of the toxin is as a rule present in the system by the time that symptoms appear, so that the proportion of cures wrought by its antitoxin compares very unfavorably with that in diphtheria. Thus we must freely affirm the justice of Professor Leech's criticism upon Behring's somewhat rash generalizations regarding the serotherapeutic millennium. Still, even here we must be cautious, for serum diagnosis may greatly widen the scope of serum treatment. The battle of the schools rages as fiercely as ever, and only the future can decide between them; but it is well that some one, speaking as Professor Leech does with authority, should temperately and dispassionately set forth the opposing views in order that those for whose sakes the fight is raging may see the goal of the combatants unobscured by the dust of the conflict.—*British Medical Journal*, Sept. 18, 1897.

#### THE TREATMENT OF UREMIC DYSPNEA BY ETHER.

GALLOIS has recently made a series of observations on this subject (*Thèse de Lille*, 1897). Being rapidly eliminated ether may be given in fairly large doses at a time without any danger of intoxication, and owing to this fact its employment under various conditions has been recommended. In cases of uremia with grave dyspnea two cubic centimeters of ether was injected night and day, as well as a dessertspoonful by the mouth in syrup between each injection. The injections must be made deeply in order to avoid necrosis of the skin. It will be seen from this that a considerable amount of the drug is given, and to this is attributed the good results obtained. A rapid and appreciable improvement is observed: respiration becomes much easier, the sensation of choking disappears, and sleep becomes possible. At the end of a few hours diuresis increases. The patients themselves become so sensible of the beneficial action of ether that they look forward with pleasure to the injections,

notwithstanding their somewhat painful character. This treatment must be continued for several days according to the severity of the case, and as a rule the interval between the injections is increased, according as the dyspnea improves. The drug may be discontinued in a week or so if diuresis have become regular. Much of course depends upon the amount of renal tissue available, for in those cases where the kidneys are severely diseased it is as apt to fail as any other method of treatment. The important point which the author emphasizes is the amount which it is necessary to give. This may vary from sixty to ninety-six cubic centimeters in the twenty-four hours, and the rapid absorption resulting from subcutaneous injection is of importance. This method differs markedly from the small doses of ether given on sugar and recommended by Eichhorst. The author has also studied the question experimentally, for he found that after producing dyspnea in an animal respiration became much more regular on giving a certain quantity of ether. He further finds that the drug produces no injurious effect on the kidneys, nor does it aggravate any existing lesion.—*British Medical Journal*, Sept. 18, 1897.

#### A STUDY OF THE ACTION OF ACONITINE ON THE MAMMALIAN HEART AND CIRCULATION.

In the September issue of the *Journal of Experimental Medicine* S. A. MATTHEWS sums up a careful experimental research made upon the hearts of dogs in the following manner:

The action of aconitine on the dog's heart seems to consist in:

1. A stimulation of the inhibitory mechanism, especially of the centers in the medulla oblongata.
2. An increase in the irritability of the muscle of the auricle and the ventricle, which leads to independent contractions of one or both of these divisions and culminates in fibrillary contractions in the ventricle.

The first of these is the only effect seen in the therapeutic use of the drug, and aconitine may therefore be considered to be indicated when it is desirable to stimulate the inhibitory center without acting on the heart muscle. Of course it has a further effect on the circulation through the stimulation of the vasomotor center, but this would appear to be of minor importance.

*MEDICINAL SOAPS IN THE TREATMENT OF SKIN DISEASES.*

The use of medicinal soaps in the treatment of skin diseases has some advantages over the use of ointments and pastes in that the superficial layers of the skin can be acted upon more rapidly and more energetically, while the effect can be easily graduated by varying the time during which the application is continued.

MULLER and GRUBE have prepared a new soft basis for medicated soaps which is named "savonal." This is prepared by saponifying olive oil with caustic potash in the presence of alcohol, the mixture to be kept cool. To a part of the clear liquid thus obtained is added very dilute hydrochloric acid in order to precipitate the fatty acids, which are then added to the remainder of the alkaline mother liquids until it is completely neutralized. The neutral soap solution is then evaporated to the consistence of an ointment. Thus prepared, the clear green soap is transparent, smells of olive oil, gives clear solutions with alcohol, water, and glycerin, and mixes perfectly with fats and many drugs.

The action of the soap can be rendered more energetic by the addition of alkalies (e.g., carbonate of potassium) or weakened by means of fats such as lanolin, but in most cases this is unnecessary.

A liquid soap basis is obtained by adding to the neutral soap solution a mixture of glycerin and distilled water and evaporating to a syrupy consistence. During a year and a half the authors have used this soap basis with good results; its absolute purity and neutrality render it superior to mollin or the soap ointment of Unna, which is unstable from excess of fat. The savonal is miscible in all proportions with many drugs, the following being a few of the combinations recommended: Carbolic acid (five per cent.), creosote (one-fourth to two per cent.), salol (five to ten per cent.), iodoform (five to twenty per cent.), balsam of Peru, ichthyol, tar, belladonna, camphor, menthol, tannin.

Combination of mercury with savonal constantly irritates the skin. Calomel may be used for syphilitic cases, and also corrosive sublimate, but the latter soon precipitates as calomel. A combination of naphthol, sulphur, vaselin, and savonal is strongly recommended for scabies "in wealthy patients." Resorcin in either liquid savonal, or the ointment with a little lanolin, is used in seborrhoeic eczema and acne rosacea. Chrysarobin,

lanolin and savonal are useful in chronic eczema and psoriasis. Iodine, iodide of potassium, and savonal may be used in gonorrhoeal rheumatism, and a solution of hydrochlorate of quinine in liquid savonal in seborrhoea with loss of hair.—*Medical Chronicle*, September, 1897.

---

*ASTHMA: ITS RELATION TO ATMOSPHERIC PRESSURE; A RATIONAL AND SUCCESSFUL TREATMENT.*

J. C. BOWIE contributes a lengthy paper on this subject to the *Edinburgh Medical Journal* for August, 1897. After discussing its relation to atmospheric pressure he proceeds to commend a new plan of treatment, which we submit for judgment to our readers.

In the treatment of asthma—spasmodic and bronchial—intra-laryngeal injections of the following solutions are used; the quantity of the solutions injected and the amount of the agents contained in each injection being in accordance with the patient's age and condition. One drachm will be found sufficient for a child from five to ten years of age, two drachms from ten to fifteen; after this from three to five drachms will suffice at each sitting.

First solution: A five-, ten-, fifteen-, or twenty-per-cent. solution of menthol in olei amygdalæ.

Second solution: Two to five minims of a two-per-cent. solution of pure crystals of iodine in olei amygdalæ, added to each drachm of the first solution.

Third solution: Five minims of a ten-per-cent. solution of olei lupuli in olei amygdalæ, added to each drachm of the first.

The action of these agents, as especially applicable to the asthmatic conditions, is as follows: The oil is an emollient and a vehicle for carrying the agents in whole or part through the circulation already described. The menthol has a powerful and stimulating action upon the mucous membrane of the bronchi and the epithelium of the alveoli and capillaries, inducing them to give off the excess of serous fluids, thus relieving their congested state; its stimulating action upon the lymphatic vessels promotes absorption of the exuded lymph, relaxing the muscular spasm of the bronchi; its astringent action promotes contraction of the cells in the alveoli and capillary walls, thus enabling the cells to resist the excessive lymph transudation; its antiseptic properties lessen the tendency to

atrophy and degeneration of cell structure; its sedative action relieves the cough. The iodine promotes the absorption of the exuded lymph, it liquefies the sputum, thereby relieving the cough, and its antiseptic properties conserve the epithelial structures. The olei lupuli is a sedative and antispasmodic, and is useful during deep spasms.

If the patient be a victim to spasmodic asthma, with deep and frequent attacks, two or three injections should be given daily of a ten- to fifteen-per-cent. solution of menthol. But when the symptoms of an impending attack become apparent, two to five minims of the iodine solution should be added to each drachm of the menthol solution, and continued throughout the attack until a week after, when the menthol solution may be again used alone. At any time, if a menthol solution is being used and signs of wheezing show themselves, a menthol-iodine solution should be substituted.

In bronchial asthma a fifteen- or twenty-per-cent. solution of menthol should be used, until the inflamed state of the bronchi is overcome. If expectoration be difficult, a menthol-iodine solution is required as well as in the asthmatic state.

Should the physiological signs of any of these agents appear, it is better to reduce the strength than to eliminate either, but always inject the same quantity of fluid.

While injecting a patient under a deep spasm, great care must be exercised lest any of the injection should pass into the stomach. Should it do so it will cause distention of that organ, and seriously aggravate the patient's condition.

The relief experienced by the patient when the injection is given under wheezing is not realized when he is under a deep spasm, nor is the injection absorbed so quickly, which is attributable to the excess of lymph in the tissue spaces and lymphatic vessels. It is often expelled when the patient is under a deep spasm, bringing with it a considerable quantity of tough mucus with more or less blood, but giving decided relief.

The time required to overcome the morbid conditions varies with the age of the patient, the length of time he has suffered, the duration, depth, and frequency of the attacks, and the changes that have been established in the pulmonary tissues.

At first, in both forms, the progress made under treatment is seriously compromised by each succeeding attack. After a time, the attacks in spasmodic asthma become less

frequent and less severe. Each succeeding attack causes less loss of weight and strength, and less nervous prostration; the sputum is gradually reduced and changed in nature; the cough has a clearer note, and the line of constriction gradually passes from the back of the thorax to about the middle of the sternum.

Also, in bronchial asthma, the catarrhs become less frequent and severe; the expectoration is gradually reduced in quantity till the asthmatic condition becomes more prominent than the bronchitis during an attack, when it follows the same order as spasmodic asthma. As the line of constriction rises, the râles and bronchial breathing are commensurate with it.

As the treatment continues, bronchial breathing with a short gasping form of respiration takes the place of the deep wheezing and spasms, and may last a longer or shorter time, until, as the line of constriction ascends, it is replaced by a loud form of bronchial breathing which is not associated with any distress. The patient does not sustain any loss of weight, and physical and nervous prostration is *nil*. Then the line of constriction gives place to a feeling of tightness in the trachea, accompanied by a loud tracheal sound during respiration, and no râles are found. This is followed by a clear, hard cough, sometimes in paroxysms, and often associated with slight hemoptysis. Coughing or a sudden increased action of the heart may establish slight wheezing of a passive nature. If the barometric charts be compared with the above, it will be found that the patient is passing over—with very little discomfort—periods during which deep asthma was experienced.

The patients are injected two or three times a day until the line of constriction reaches the upper part of the sternum, when once a day is sufficient; but if the symptoms should show any signs of exacerbation, twice a day is necessary. At this stage intermittent treatment will suffice—that is, injections being given only when a cough and feeling of tightness trouble the patient. The patient's condition undergoes great improvement; he gains flesh, becomes more erect, and speaks with a clearer voice; the thorax becomes clothed with a proper muscular padding, and has a greater range of action. The age of the patients that have come under Bowie's care ranged from five to forty years. The length of time each had suffered varied from a few months to over fifteen years. The

time taken to overcome the conditions varied from a few months to over two years. The younger the patient and the shorter the duration of the disease favor early resolution.

Within certain limits bronchial asthmatic cases are no more difficult to resolve than spasmodic. The resolution of the asthmatic state, under treatment, takes place in the inverse order to that in which it was established. This treatment, if assiduously carried out, permits the patient, even in severe cases, to take outdoor exercise almost daily, and in time enables him to follow without interruption his daily occupation.

#### USE OF THEOBROMINE IN THE ASYSTOLE OF OLD PEOPLE.

Dr. E. BARONAKI considers theobromine to be the remedy of choice in the asystole of old people. It brings on rapidly a diuresis amounting to four, five, or six liters, and wards off the symptoms of uremia. This marked diuresis is especially noticed in the chronic asystole so frequently observed in old people accompanying edema, anasarca, and ascites. In the pulmonary or hepatic forms theobromine does not seem to have the same diuretic action. Diuresis may come on the very evening of the administration of the drug, but most frequently the following day. It leads to a marked improvement, the signs of uremia disappear rapidly, the respiration becomes better, and the patient is out of danger for some time.

The most marked diuresis is obtained when the use of theobromine has been preceded by digitalis. Association of theobromine with caffeine or with salicylate of sodium does not give better results than theobromine alone.

After venesection or scarification theobromine seems to recover its diuretic properties. The author believes in large doses. With two grammes (thirty grains) no appreciable diuretic effect is obtained, three grammes (forty-five grains) at least being necessary. Four- or five-gramme doses do not increase the diuretic effect. It is not advisable to continue the great diuresis for any long time. When the dangerous symptoms have disappeared the theobromine should be discontinued and iodides given. Dr. Baronaki has noticed as inconveniences of the prolonged use of theobromine, vomiting, nausea, vertigo, and phenomena of excitement. He has also observed an increase of the quantity of albumen in the urine.—*Medical Chronicle*, September, 1897.

#### THE PREVENTION OF PNEUMONIA FOLLOWING ANESTHESIA.

In the *Boston Medical and Surgical Journal* of September 23, 1897, WHITNEY points out that of late the attention of the profession has been called to the frequency of pneumonia after operations where anesthesia has been used. Whether it is really more common to-day than in the past is doubtful; but there are two factors which make it appear so: With the larger number of surgical cases a greater number of pneumonias may occur and yet the percentage remain the same; with the perfection of asepsis other infectious processes have been eliminated to such an extent that this one has an opportunity to develop unobscured, and thus has come into greater prominence.

Attempts have been made to prove that there is something peculiar to the pneumonia after ether, and directly attributable to that agent, and the name of "ether-pneumonia" has even been proposed. But the most careful observations have shown that the disease in the most fatal cases differs in no way from the ordinary fibrinous form, and the cultures have shown it is caused by the same class of micro-organisms, at the head of which stand the pneumococcus.

While all the ways by which these bacteria can enter the system are not known and their introduction by means of the circulation cannot be denied, still their direct route is through the air passages, and this is a perfectly rational assumption of their mode of entrance.

In the distribution of these microbes it has been found by Sternberg and others that they are present in the mouths of healthy individuals. It is probable that in such cases under ordinary circumstances the organism can render their action harmless. But there are exceptional conditions which render a person susceptible to pathogenic bacteria; and experimentation upon animals has shown that prolonged and profound etherization is one of the conditions which increases this liability to infection. The patient, therefore, is in the most favorable condition for the development of the germs if they can find entrance, which is favored by the inhalation of mucus and saliva in the unconscious state.

While much cannot be done to prevent this increased susceptibility beyond as short and light etherization as possible, the thorough disinfection of the mouth before anesthesia is within the control of the surgeon, and

should be as carefully attended to as the breast or leg that is to be amputated.

The details of this should be a thorough aseptic cleansing of the mouth, nose and pharynx at least twice—once in twelve hours and again immediately preceding anesthesia. Each time the teeth should be brushed, then the mouth rinsed, especially about the roots of the teeth, and the throat gargled several times with a warm solution of chlorinated soda:

℞ Liq. sodæ chlorinat., f 3 iij;  
Aq. menth. piper., f 3 ij;  
Glycerini, f 3 ij.

Afterwards the pharynx and tonsils are to be sprayed with a solution of:

Peroxide of hydrogen, 1 part;  
Water, 3 parts.

Then the nose is to be douched with a pint of warm saturated aqueous solution of boric acid, to which half a teaspoonful of salt has been added.

As a last detail the cone or sponge used for the anesthetic should be sterilized for each case.

It may be urged that to carry out the above in every case would be exacting, and it would be very well to do it if it was certain that the organisms entered in no other way. Our knowledge, unfortunately, does not permit at present a selection of cases for which such a course should be reserved, and therefore every patient has the right to demand of the man in whose hands he so implicitly places his body and life that he should be given every chance for a rapid recovery. And he is entitled to the benefit of every detail, if it can be shown to be consistent with the line along which the science of surgery is advancing.

#### CLIMATIC TREATMENT IN GRAND CANARY.

It is not often that the editor of the *Gazette* calls attention to comparatively unknown health resorts by the use of progress derived from climatological articles, but an interesting paper by MELLAND in the *Medical Chronicle* for August, 1897, is worthy of perusal.

The author mentions the fact that in dealing with cases of early phthisis, which first make their appearance during the summer, that the nearness of Canary, ease of getting there, and cheapness of living (when contrasted with Egypt and fashionable parts of

the Riviera) should be kept in mind by all medical men, and that such cases should be sent out at once. If they come to Canary they will find a dry summer temperature, as healthy or healthier than the winter. They can go straight up to Monte and remain there till October. When their symptoms have disappeared for the time, and the disease, at any rate, is temporarily arrested, they can then settle what their future course of life shall be. Patients often cannot be sent away in this sudden manner to a more distant healthy climate, such as Australia or South Africa, owing to the costliness of the proceeding; they are frequently allowed to remain on at home until it is too late in the autumn, and meanwhile their disease progresses. Towards November, perhaps, they get suddenly worse, and are then ordered off at once; they arrive in Canary, and what might have been a curable case if sent some months earlier is now incurable, and death is merely a question of so many years. The greater number of invalids arrive in November. To recapitulate the effect of the climate on phthisis, he has found it very beneficial in both the active first stage and the quiescent first stage.

In chronic fibroid phthisis without cavitation there is usually improvement after living two or three years in the island continuously. If cavities are at the same time present, there is usually drying up of these and diminished expectoration; the dryness of the air favors this. Several patients of this class have settled down to life in Grand Canary, have taken a small villa at Las Palmas to live in from October to June, and have lived at an altitude station for four months in the summer (usually from 1200 to 1800 feet). Three or four have got well enough to settle down to work in Canary; one or two have been there many years. The climate seems particularly suited for chronic fibroid phthisis.

In the more serious cases of the third stage of chronic tubercular phthisis with considerable cavitation, where a continuous residence is made in the island, life appears to be prolonged, probably from two to five years longer than if the patient lived at home and merely went away during the colder part of the winter. The cough, to a large extent, seems to go away, and the patient complains little about it; but the hectic fever remains to some extent, and the patient gets thinner and weaker, and seems to fade away from general marasmus with, at the last, edema and cardiac insufficiency. These serious cases

are not cured by being sent to Canary or anywhere else.

In first-stage phthisis characterized by hemorrhage the author has seen some very favorable results, and has come to look upon hemorrhagic cases as more hopeful than any other variety of phthisis. This has been the experience also of Madeira, and no doubt is also the general impression amongst practitioners, as regards prognosis generally in the various types of phthisis, that disease in which prognosis is so very difficult in any particular case. In the race for health the many fail, the few succeed, and the race is not always to the stronger. Two cases with very considerable hemorrhages, who wintered here six years ago (1891) for one winter only, have apparently become quite cured, and followed their usual occupation at home since, without return of any symptoms so far. (One of the cases had severe bleeding—sixty ounces in thirty hours—and was at the point of death from loss of blood; but although the case came out with a provisional diagnosis of fibroid phthisis, and there was dulness at the left pulmonary base, it was doubtful how far it was tubercular or exactly where the blood came from. The patient was then a child, and is now a robust adult.)

Melland thought at one time that the coast was better—theoretically, at any rate—for hemorrhagic cases than the hill stations; but he has now changed his opinion, for in several hemorrhagic cases he has seen more rapid improvement take place at stations of 1300 and 1800 feet in the summer-time. As in other cases of early phthisis, no doubt the coast is better from November till May, and the mountains afterwards. Hemorrhage does not seem to occur often at sea in early phthisis. He has only known one case out of many have any bleeding on the voyage to Canary.

In early phthisis with asthmatic symptoms and hemorrhage combined a more sedative climate like Madeira is perhaps indicated, though he has seen one case improved in Canary. The asthmatic symptoms, however, became bad again, so he was recommended to go to New Zealand to settle.

The climate is favorable in scrofula.

In laryngeal phthisis for five years he saw no case receive any benefit whatever. All these cases were severe, and had also severe lung lesions. The author does not know why they were sent out. During the last two years he has seen one case very much improved and two cases with very slight ulcera-

tion on the cords quite healed. One of these latter cases has also got rid of all his apical symptoms and looks perfectly strong again, and, as he has settled down to work in Canary, the author does not think he will have any recurrence. (He has been in perfectly good health now for eighteen months.)

Cases of tuberculosis of the intestine should not be sent to the islands on any account—they are usually aggravated.

Chronic bronchitis is usually much benefited by the Canary climate, and also chronic bronchitis with emphysema and dilated heart. Such cases are able to return home for the summer months—from June to October—but we find that they return to Canary with great regularity as winter comes on. Two such regular visitants Melland has seen return now for seven winters who would probably have not lived through more than two winters if they had spent them at home. In one of these cases the ankles became first markedly edematous eight years ago when on the Riviera, and although the edema returns with a subacute attack of bronchitis occasionally, it is not so marked as it was eight years ago.

In heart disease accompanied by occasional lung complications the climate is very favorable. A patient of the author's having lived two winters at the hotels, took a house and settled down to life in Canary, going home each summer. He has now completed his fourth winter, and for the last two years has felt perfectly strong. He has wintered away from home for the last fifteen years on the Riviera, in Australia, and elsewhere, but never was the cardiac compensation so complete as it has been the last two years now that he has become a regular Canary resident. He has forgotten that he was ever an invalid. These cases do well at 500 to 1000 feet elevation in the winter as well as in the summer.

Pure spasmodic asthma should not, as a general rule, be sent to Las Palmas or any of the coast resorts. In three cases out of four it is very much aggravated, and the author has had to send a large number of cases away shortly after arrival. The same may be said of Orotava and most of the ocean resorts. This seems to be caused by the large amount of ozone in the air caused by the break of the surf and the stimulative effect of the north-east trade wind. The worst wind of all for asthmatics is the very dry east wind from the Sahara. In only two or three cases has he seen improvement, and these patients have usually returned to the island. The percent-

age of ozone and the force of the wind rapidly diminish as we leave the coast, and one or two miles inland or six miles away at the Monte many asthmatics do well.

The climate which is required in Bright's disease being a mild, dry climate free from sudden changes, especially sudden depressions of temperature, is found nowhere better than at Las Palmas during the winter, from October to May. Both in Bright's disease and rheumatism it may be strongly recommended in preference to the more sedative marine climates. The less cloud and the more sunshine present at Las Palmas in the winter make it superior to Madeira and Orotava. Stations on the south side of Teneriffe, as Santa Cruz and Guimar, are suitable; but not those on the north, as the action of the skin is not so free under the "parasol" of cloud. The dry mountain summer climate in Canary, at Monte or Galdar, or above the clouds in Teneriffe, is even superior to the winter climate from its greater dryness, and the dieting can be carried out with perhaps less hardship to the patient than at home owing to the variety of vegetables and fruits. Fish are plentiful, and are taken up country daily; but the quality of fish in Canary is far inferior to what is caught in English waters. The grape cure can be practised from June to October in Monte. The best grapes cost about a half-penny a pound. Melland has seen four cases of persistent albuminuria in young adults under thirty years of age quite cured in Canary.

In rheumatism Melland has very great belief in the Canary climate, both in convalescence from the acute fever and also in chronic rheumatism. Both the position of the town of Las Palmas on a calcareous raised beach and the atmosphere are dry, and he believes that the coast resorts during the winter and the mountain resorts during the summer stand on a higher footing in the treatment of rheumatism than they do in the treatment of any other disease. There are, however, at present no modern hydropathic arrangements whatever.

---

*THE INFLUENCE UPON NERVOUS AFFECTIONS OF OPERATIONS UPON THE FEMALE PELVIC ORGANS.*

The general trend of medical opinion of late years has been pretty steadily against the efficacy of operations upon the pelvic organs, especially oophorectomy, as a cure for mental or nervous affections, always ex-

cepting those cases where diseases of those organs demand such operation, independently of the nervous condition. At a meeting of the Association of American Physicians, in 1891, Dr. Wharton Sinkler, of Philadelphia, took the ground that it was unjustifiable to remove healthy ovaries in cases of nervous disease, and the late Dr. Lusk, of New York, said that he was tempted to regard such a proceeding as malpractice. A recent inquiry conducted by Drs. ANGELUCCI and PIERACINI, of the Provincial Asylum of Macerata, Italy, has afforded considerable information in the way of the accumulation of statistics of cases in sufficient number to warrant certain definite conclusions.

The data which they present are based upon reports made to them by heads of public and private asylums and psychiatric clinics in various countries, embracing a total of 115 cases in which surgical operations were performed upon the female sexual organs, either healthy or diseased, to combat some nervous disorder, or to remove diseased organs. One hundred and thirty-seven of the asylums and clinics interrogated had had no cases of the sort. Out of seventy-six alienists, directors of asylums or clinics, fifty-six more or less strongly disapproved of such operations, twelve had not had sufficient experience to warrant a personal opinion, five were uncertain, and only three favored such operations in the treatment of hysterical conditions.

Of the 115 cases, six were subjected to a simulated operation for the relief of hysterical conditions. Of the remaining 109 cases, sixty-five had healthy organs removed for the cure of nervous conditions, eighteen nervous patients had diseased organs removed, and twenty-six women neither insane nor hysterical had diseased organs removed. Forty-one cases of hysteria had healthy organs removed on account of the nervous trouble; of these seventeen became insane, ten grew worse, eleven were unaffected, and three were cured. Eighteen cases of hysteria had diseased organs removed; three became insane, six were unaffected, and nine were cured. Twenty-four women neither hysterical nor insane became insane after diseased organs were removed, and two others became neuropathic. Twenty-four insane women had healthy organs removed for the cure of their insanity; nineteen grew worse or were unaffected, and five improved or were cured. In only seventeen cases, therefore, were the results favorable, and of these only three were cured of hysteria or other nervous dis-

turbances by the removal of healthy organs. Inasmuch as six cases of hysteria were apparently cured by simulated operations the investigators naturally inquire how far, in these cases where actual operation was done, the influence of suggestion may have been felt.

As a result of their inquiry Drs. Angelucci and Pieraccini conclude that the removal of the uterus or its adnexa, if in a healthy state, is to be proscribed as a means of treatment of hysteria or insanity, and that the existence of hysteria is almost a contraindication for any serious gynecological operation. If any such operations are undertaken the indications must depend upon the gravity of the uterine or ovarian disease, and not upon any hope of a favorable influence upon the nervous conditions; the only favorable influence upon these latter conditions is in the way of suggestion. If all other means have failed in combating hysteria, a simple incision, simulating a laparotomy, may sometimes be admissible by way of suggestion.

Taking the statistics, as the present writers have done, from reports furnished by asylums and psychiatric clinics, it is possible that the proportion of cases injuriously affected by such operations is unduly large, since the physicians in charge of such institutions might have less opportunity for observing the cases which were entirely cured of any nervous or mental trouble after the operation. Nevertheless, any serious cases of nervous or mental trouble which were cured by operation would naturally have come under the observation of these men during the time when they were suffering from such trouble, so that the proportion is really nearer the truth than it might at first seem. Furthermore, as is well known, the statistics of cases from surgical reports only are too often based upon the immediate results of operation, without waiting to note the later developments in regard to any nervous troubles. It is therefore safe to accept the conclusions of Drs. Angelucci and Pieraccini, as indorsing the belief that the removal of healthy organs for the relief of nervous or mental troubles is wholly unjustifiable—*Boston Medical and Surgical Journal*, Sept. 23, 1897.

#### PALLIATIVE AND OPERATIVE TREATMENT OF FISTULA IN ANO.

BLAKE (*Boston Medical and Surgical Journal*, Sept. 2, 1897) makes an admirable addition to the literature of this subject. He

takes up the definition, etiology, extent, and symptoms of fistula *in ano*; then proceeds to a consideration of the anatomy and blood-supply of the part.

Treatment is divided into non-operative and operative. Under non-operative the methods are numerous, but all may be classed under one of the following heads: Simple cleanliness; dilatation of external opening and packing with gauze; application of caustics; introduction of ligature, preferably elastic.

The cases to which any of these methods are applicable are those not attended with acute inflammation, or the presence of much pus; those which are not extensive; those which present a direct tract, without diverticula or branches; those which do not extend through the levator ani muscle; and, probably also, those which are not tubercular, or which do not show symptoms of being tubercular, though to the exclusion of this latter class some writers would disagree.

It is obvious that this classification limits to a marked degree the non-operative treatment; but beyond these limits the writer is convinced that palliative treatment at present should not be advised or undertaken. Exception, of course, is made of those rather rare cases in which on account of age or the general condition of the patient there is a definite contraindication to operation, or in which the patient refuses operation, and desires treatment, which is given with the distinct understanding that it will probably be insufficient.

It is a fact that certain superficial or marginal fistulæ following fissures, or slight trauma, or very small abscesses, may heal, and heal permanently, if left to themselves and kept perfectly clean. Such cleanliness, however, must be persistent and scrupulous. Not only must the parts be washed at least once daily, and more often in warm weather, but they must be cleaned carefully after each movement of the bowels, and should be irrigated with some mild antiseptic or astringent, such as myrrh wash, or dilute liquor plumbi subacetatis. After the washing they must be made, and what is of great importance maintained, perfectly dry. After wiping out the sinus, filling it with some inert powder, or with powdered boric acid, is at times of undoubted benefit. Such treatment is monotonous and necessarily of long duration. The cases are rare in which it could be advised, and the patients who would carry it out are still rarer.

If packing with gauze is added to the cleansing we have a method which will undoubtedly be sometimes followed by success. The method is common enough in the sinuses which follow operations in other parts of the body, and owes whatever efficiency it possesses to the cleansing which precedes it, and to the slight irritation to the sides of the sinus to which the packing gives rise. If carefully and conscientiously carried out, it compels whatever healing takes place to progress from the bottom of the sinus upward, and it prevents pocketing of the discharge; it also helps to prevent the introduction of dirt either from the rectum or externally. Gentle dilatation of the external orifice, with dressing forceps or director, will facilitate the introduction of the gauze and the escape of the discharge. The frequency of the dressing varies with the amount of discharge, but will average approximately once in two days. Care must be taken not to pack too frequently or too solidly, as the former procedure may mechanically interfere with healing, and the latter prevent drainage. Iodoform gauze is unquestionably the best material, though baked gauze dusted with nosophen or aristol is also good.

The application of caustics is a direct step towards removal of the cause of the fistula, and exciting union by adhesion or counter-irritation. All sorts of caustics have been recommended. Until late years nitric acid has been much used. It has been supplanted by ninety-five-per-cent. carbolic acid, which presents decided advantages over it—among others, that of being far less painful, and of being able to act efficiently without the formation of so deep a slough. The fistula should first be cleansed by the injection of peroxide of hydrogen in 15–30 volume strength, or of permanganate of potash, and dried. A wisp of absorbent cotton is tightly wrapped about the end of a fine probe or wire, previously moistened a little to help the cotton to adhere. The cotton is saturated with ninety-five-per-cent. carbolic, and introduced into the sinus to the bottom, or to the internal orifice, and is then rotated and rubbed against the sides. Care is taken to prevent the healthy skin in the neighborhood from being moistened with the acid. The writer has usually applied the acid once in three days, but it is probably better to apply it oftener. In two or three cases the progress at first was rapid and satisfactory, but later on the more superficial part of the sinus was more obstinate in healing. In one case it

failed entirely, though it is only fair to say that this case had been operated on before, and has since been operated upon again, and is still not entirely healed. It was a good example of a case in which the palliative treatment should not be advised. It was undertaken as an experiment. Sinuses without greatly thickened walls are particularly favorable for this method of treatment.

The objections to this method are the possibility of using too great a quantity and producing too deep a slough. In obstinate cases it may be advantageously combined with a packing of gauze.

The use of some sort of ligature for the cure of fistula has been recommended for centuries. Various materials have been used. It is certain that the elastic ligature possesses more of the qualities necessary for success than any of the others. The elastic ligature in the past, however, has not been without its dangers. One case in which it was used died with the symptoms of septicemia, and two others developed secondary abscesses, though they were purposely confined to bed in the hope of avoiding such complications. These cases occurred some years ago, however, and since then the elastic ligature has been employed at the Boston Dispensary and at both the hospitals in Boston with perfectly satisfactory results.

The cases adapted for ligature are complete fistulæ, of not too great a depth, without diverticula, and past the stage of acute inflammation. The operation consists of passing the ligature through the fistula, and fastening the ends tightly together. The only difficult part of the operation is the introduction of the ligature. For this purpose several needles and probes have been devised, and Allingham has invented a formal suture carrier on a handle, in which the end of the ligature is carried through a guarded eyelet. These instruments are unnecessary as a rule. The writer in one case passed the ligature easily by simply bending down the tip of the ordinary silver probe over the end, then passing the probe and ligature through the fistula. The ligature is then put on the stretch, and either tied or, what is more easily done, caught between the edges of a split shot, which is then compressed by means of a strong pincers. It is at times advisable to dilate the sphincter gently, and it is often surprising to find how much the sphincter can be dilated without pain, if much care and a little time be devoted to the task; this is, of course, in the unetherized patient.

The ligature should be drawn as tight before fastening as its strength will allow, and it is best to test this before inserting it. If the fistula be a deep one, it is sometimes advisable to insert a small piece of gauze between the shot and the skin, to spread the pressure over a little greater area.

The ligature cuts out in from five to ten days, the fistula healing behind it, sometimes with remarkable rapidity; the tract at times is more than half healed before the ligature comes away. The pain varies a good deal; as a rule it lasts rarely more than forty-eight hours, and the patient may be on his feet the entire time. The most serious objection to the ligature is in choosing appropriate cases, for the simplest fistulæ are often found upon close investigation to possess unexpected diverticula.

The choice in operative treatment is practically limited to two methods: Free incision, with granulation from the depth of the wound to the surface; removal of the fistulous tract by dissection and uniting the wound by sutures to secure healing by first intention.

The second method may be modified in some cases by curetting instead of dissection.

These methods may be briefly described as incision and excision. In preparation for any operation on fistulæ the patient's bowels should be moved by cathartics, preferably saline, on the day preceding the operation, and, if possible, not more than two hours before ether is administered. The diet for a day or two preceding should be exclusively meat broths. The position of the patient on the table may be either that of dorsal lithotomy, or on the side on which the main opening of the fistula is situated, with the knees flexed sharply on the abdomen. Mechanical cleanliness must be encouraged by shaving, and antisepsis rather than asepsis sought for. So far as possible fistulæ should not be operated upon while acutely inflamed.

The sphincter must be always dilated fully, both to facilitate the discovery of the internal opening and to hasten healing. The fistula, or if there be more than one, the largest<sup>1</sup> of the external openings, is then investigated with a fine probe, particular attention being directed towards the discovery of branches or blind pockets. The opening into the bowel is often difficult to find, and it is the rule, rather than the exception to find that the tip of the probe can be made to travel up and down the rectal wall for some little dis-

tance without perforating it. The finger of the unemployed hand is now introduced into the anus and the orifice sought for. It is better not to force the tip of the probe through the mucous membrane if this can be avoided. It is advisable first to slit up the sinus from the outside a little at a time, with knife or scissors, in the hope of finding the inner opening as the operation progresses. The more carefully and thoroughly the incision is carried out, the better will be the chance of rapid and complete healing. Granulations or thickened sinus walls must be thoroughly removed by knife or curette, and small pus pockets or diverticula cleaned and scraped. The external sphincter may be freely incised in cutting the internal sphincter. It is desirable to leave part of its fibers intact, if this be possible; if not, it is absolutely necessary to cut through it at right angles, not obliquely, and it must never be incised in more than one place on pain of certain incontinence. Particular care must also be taken to avoid cutting the sphincters anteriorly in women, at the point where the fibers decussate, and are continued forward on the side of the vagina.

The simplicity of the operation, in the average case, tends to make the operator less careful in its execution. As the result depends essentially upon its thoroughness, too much emphasis cannot be placed upon the necessity of discovering and laying open all branches and diverticula, however short they may be. This can only be done by examining carefully the floor and walls of the sinus progressively.

When the internal opening is well above the upper sphincter, three methods may be considered: The sphincter may be cleanly incised at right angles and left to granulate; or it may be incised and held together by a deep suture; or the elastic ligature may be introduced, as suggested by Allingham, at the bottom of an incision which reaches to the lower margin of the sphincter.

All bleeding should be stopped as far as possible by temporary packing. In superficial fistulæ it is rarely necessary to tie vessels if the snap forceps be allowed to remain on them for a few minutes. After determining that the floor and walls of the wound are thoroughly cleansed, it should be packed, not too snugly, with a thin layer of iodoform gauze, and a pad and T-bandage applied. Some writers doubt the desirability of a suppository, but in an operation of any considerable extent it is better to insert it as a

matter of precaution. A quarter-grain morphine suppository is sufficient.

Horseshoe fistulæ should be thoroughly opened, but should be incised into the rectum in only one place, that opposite the larger opening if two exist. If there are multiple openings externally, paths of communication between them must be sought for, and can usually be found; they should then be opened from one to another and finally, in one place, into the rectum. In some cases the openings are so numerous, and the tracts so deep, that it is very advisable to do the operations at two sittings, attacking the deeper portions first and simply dilating the other orifices. Much ingenuity has been exercised in determining the most advantageous methods of making the incisions between the various orifices, but cases vary so much that no general rule more than the above can be laid down.

The fistulæ which are at once the most dangerous and most difficult are those which perforate the levator ani muscle and penetrate the subperitoneal space in the pelvis. To open these thoroughly demands a very deep and often bloody incision, but unless opened thoroughly the operation is ineffectual, for the levator ani closes down and retains the discharge above, tending to the formation of the so-called hour-glass fistula. If the fistula is in the usual position, posterior to the anus, there is much less danger of wounding the perineum. If it is anterior, however, this possibility must be carefully borne in mind. The opening in the levator ani may be stretched with Bigelow's dilator advantageously, and the packing must be inserted to the bottom. Old, deep fistulæ have been found to lead in all directions above the levator ani muscle and triangular ligament, and at times to perforate the bladder, the rectum, or vagina.

As a rule, the dressing should be changed on the second day after the operation, and each day after that. Thorough cleansing is essential, and it is better to use peroxide of hydrogen, permanganate of potash, or corrosive sublimate. The packing should be carefully introduced to the bottom of the wound, and in small quantity. Care should be taken not to allow pocketing of the discharge, nor to interfere with the granulation by too vigorous dressings. The bowels should not be moved before the fourth or fifth day, and an enema of warm sweet oil should be given and retained for one or two hours to soften the feces, before the soap-suds enema

which is intended to clean out the rectum. The diet after, as before, should be exclusively animal broths, for at least four or five days, since these produce least fecal mass. The patient should lie preferably on the side opposite the fistula.

The after-treatment is as important as the operation. The patient should be kept either in bed or lying down while there is granulating area of any considerable extent, as the motions of walking are not conducive to healing. In packing the wounds, iodoform gauze has given the greatest satisfaction.

The duration of the granulating process varies extremely. It is rarely less than three weeks, except in the most superficial cases, and often reaches three months and more.

Whenever the internal sphincter is involved the patient must be expressly warned beforehand of the possibilities of incontinence. Rarely is it true of solid feces, but often of gas or liquids; and not infrequently this is a permanent condition. An insufficient sphincter, for which the owner is unprepared, is a memento of the operation which is not relished by either patient or surgeon, and is a poor exchange for a fistula which may have been but a slight annoyance.

Sinuses in various parts of the body have been excised and sutured for years, and there is no good reason why favorable cases in the ischio-rectal fossa should not be similarly treated. The essentials of the operation are that it shall be possible to remove the cause of the sinus, to convert it into a clean wound, and to keep it clean. If these conditions are obtained and maintained, the result will be healing by first intention. The type of fistula therefore to which this method is applicable is non-inflammatory fistulæ, of moderate extent, with few branches; and also blind internal fistulæ of all varieties. In one case the writer has sutured a horseshoe fistula with excellent result. The fibrous walls must be removed, preferably by dissection, sometimes with the curette. Granulations or pockets must be cleaned out with curette or Paquelin cautery, hemorrhage stopped, and the walls approximated by deep sutures. Silk is the material usually used. It is advisable to introduce each suture so that it encircles the wound and does not pass through its sides. For this purpose the so-called fish-hook needle has been invented. A strong needle with a sharp curve is essential, a Hagedorn preferably. The sutures vary in number according to the length of the fistula, and should be inserted at least as often as

half-inch intervals. Sutures are removed in from three to six days; the dressing should be a wet corrosive pad, 1:3000. The pain following the operation is apt to be greater than in simple incision. If the case is not progressing favorably, heat and redness increase, with the signs of retained pus; the stitches are removed alternately, and even in these cases a considerable amount of union is often gained. It is sometimes advisable, especially in old fistulæ, to insert an iodoform bougie into the bottom of the wound, and sew the sides together around it.

In superficial fistulæ it is almost invariably successful. In deeper cases it sometimes succeeds unexpectedly. It has never found much favor among English operators. It would seem that the operation of excision for fistula will find a larger field in the future. Its obvious advantage is in the time gained in convalescence.

#### THE SURGICAL TREATMENT OF ENLARGED PROSTATE.

HELFERICH, of Greifswald, in introducing the discussion of this subject (*Trans. Cong. Germ. Surg.*, April, 1897), referred to the fact that although operations on the several organs had been practised during the last four years all over the civilized world, these operations are still *sub judice*. The statistics collected by Bruns embrace 148 cases, in which both testicles were removed; there were twenty-three deaths, and in eighty-three per cent. of the remainder the prostate is stated to have diminished in size. Socin, of Basel, collected 175 cases, in four-fifths of which there followed decided atrophy of the prostate; in three-fourths the contractility of the bladder was regained; in forty-five per cent. the urinary functions were restored to the normal. Death followed in 13.5 per cent. Kohler reports seventy cases in which a resection of the vasa deferentia was performed; of these, three died, thirty-six were restored to health, sixteen were improved, and fifteen remained *in statu quo*.

Experience has shown that although the soft glandular prostate is more likely to diminish in size after either of the above operations, it is not possible to forecast the result in any individual patient; and that in a certain number of cases the operation may be followed by mental depression of considerable gravity. After reviewing the other operative measures, the author concludes that although a more certain and more radical

cure may be attained by those which are directed against the prostate itself, there are still cases in which the "sexual operations," with all their drawbacks, are to be preferred and are to be recommended to the patient. Socin pointed out that the diminution in size of the prostate, observed after castration, is entirely dependent upon the emptying of the veins; diminution of the prostate has never been observed on post-mortem examination.

Borelius, of Karlskrona, submitted the statistics of 102 cases, in which one or other of the sexual operations had been performed by Swedish surgeons (double castration in fifty; bilateral resections of the vas deferens in forty-six; castration on the one side and resection of the vas on the other in six). The results showed that sixty were improved, sixteen were not improved, four were uncertain, and twenty died. Inasmuch as forty-three out of the sixty who were improved represented cases of uncomplicated retention, and would probably have benefited quite as much without operation, one can only characterize the results here given as very unreliable.—*Centralblatt für Chirurgie*, July 17, 1897; *Edinburgh Medical Journal*, October, 1897.

#### A SERIES OF CATARACT OPERATIONS (ONE HUNDRED AND FIFTY-EIGHT).

RANDOLPH publishes a careful statistical contribution to this subject in the *Bulletin of the Johns Hopkins Hospital* for October, 1897. Two of the cases are especially interesting as being instances of maniacal excitement, possibly due to the use of atropine after the operation. The first case was a colored man, operated upon in the poorhouse of Mineral County, W. Va. He was seventy-five years old and had been practically helpless from cataract for a year. Atropine was instilled immediately after the operation. The next morning the physician was sent for and reported to the author that the patient had gotten up during the night, torn the bandage off, secured a razor, cut his throat in several places, and was bleeding profusely when found. In the excitement which followed the eye was forgotten, and it was some time before the bandage was replaced. He was quieted, and seven days later—that is, on the eighth day after the operation—he disappeared from the poorhouse, and two months afterward was seen by Dr. Hoffman twenty miles distant, where he was chopping wood and apparently getting along with absolute comfort.

The other case was also a very old colored man, eighty-eight years of age. The operation was simple extraction, and atropine was instilled as usual at the operation. Before daybreak of the next day he was a raving maniac and had to be tied down to his bed. His bandage was torn off several times, and he was incessantly tossing his head from side to side, until that too had to be secured so as to be as far as possible immovable. He did not recover his reason for a week, and all that was done was to apply hot moist compresses to the eye. When he became rational and the reporter was able to get a satisfactory view of the eye, he found a rather small pupil, a slight prolapse, but very little pericorneal congestion. On the tenth day he seemed to be completely himself again, and as the eye evidently needed a mydriatic, one drop of a solution of atropine (four grains) was instilled, and the nurse was instructed to repeat the dose at bedtime. When he returned to the hospital the next day he found that during the night the patient had jumped out of the window, twenty feet from the ground, scaled a high iron-spiked fence, and was making off when overtaken by an orderly. Notwithstanding all this exposure he obtained 20-70 vision. Nothing was done for the prolapse, which flattened out entirely.

Another interesting case was where the anterior chamber remained open for seventeen days. The operation was the combined one, and the wound had united about halfway up on one side, and the rest of the incision remained open. More than once during these seventeen days a spatula was passed beneath the corneal flap, and it was easily seen that no union had taken place. The operation so far as could be seen appeared to have been normal—that is to say, there was not the slightest hitch in any of the steps. Atropine and compress bandage were employed, and two weeks after he left the hospital his vision was 20-200. Eight months later he returned to the hospital with serious iritis, and since then vision has been lost, though he still has light perception.

Iridectomy was performed in 102 cases and simple extraction in forty-two cases. Soft cataract was operated upon by needling in three cases.

In thirty-one cases the vision was not tested. Three of these cases were in very young children, and any subjective test would have been very unreliable. The remaining twenty-eight were some which he had operated upon at a distance and most of

whom he saw only once after the operation. A number of cataract glasses were sent to them from which to make a selection, and in this way he learned to what extent the operation had benefited the patient. The operation and healing process were uncomplicated in all of these cases and all obtained useful vision.

The failures were as follows:

In Case 54 the operation was smooth, and when the bandage was removed she could see large objects in the room. This was on the seventh day. Two days later iritis of a very sluggish character developed, and in spite of all treatment ended in closed pupil and light perception. Dr. Harlan, of Baltimore, operated on the other eye and obtained good vision, but the operation was also followed by iritis.

Case 72 had an exactly similar history.

Case 95 was one which the writer treated for several months for dacrocystitis. Her left eye had been operated upon by a New York oculist two years previously, and the cause of the failure in the case of that eye was no doubt the same as in the case of the eye upon which Randolph operated, for both eyes were affected with dacrocystitis. When first seen she had a fistulous opening which had been discharging for several months. Before operation she was under treatment for at least five months, during which time the fistula had closed and the epiphora had almost disappeared. The cornea sloughed within a week after the operation.

Case 137 was that of a man eighty-one years old. On opening the eye on the third day there was a very offensive discharge on the bandage and between the lids, and beginning clouding at the edge of the corneal wound. Vigorous local and constitutional treatment, however, prevented the corneal trouble from extending, and he was left with a clear cornea and closed pupil. The author thinks he could have converted this failure into a success by iridotomy, but a few days before the proposed operation he was attacked with pneumonia and died on the eighth day.

The last case was that of an old colored man.

In one case (male, both eyes 67 and 68) the patient had good light perception, but after the extraction of the cataracts it was observed that while he could move about somewhat better his sight continued very poor, and this was explained by the existence of optic nerve atrophy in both eyes.

In two other cases a cataractous lens (congenital) had undergone calcification and presented a bright white mass in the pupil. The operation was simply for cosmetic purposes.

As to prolapse of the iris: In the forty-two cases of simple extraction there were five prolapses. In three of these cases nothing was done; under a compress bandage and atropine the hernia in one smoothed over and the patient now has vision 20-40. In one case the prolapse got worse from day to day till it nearly filled the wound, and it continued bulging more and more. There was no hernia on the second day when the eye was inspected, but the patient had a little gush of tears that night followed by pain, and a small hernia was visible the next day. On the eighth day, fearing that the eyeball would be permanently disfigured (to say nothing of loss of sight), the protruding iris was cut off. There is now not the slightest ectasia of the cornea so far as can be seen, and the patient has 20-30 vision.

In these last two cases lacrimation and photophobia were present to a marked extent, and some little pain was felt at the time when the prolapse occurred, but after this pain was conspicuously absent. So far as could be seen there were no evidences of infection in any of the cases of prolapse. By evidences is meant cloudy media and exudates. The absence of infection in these and similar cases is to be attributed to the fact that the wound is filled with the protruding iris and probably there is no way for the bacteria to make entrance into the anterior chamber. The profuse lacrimation which is usually present must be regarded as more or less protection from a mechanical point of view—i.e., to some extent in washing away bacteria. An examination of the statistics of simple extraction will disclose the fact that the failures are as a rule not associated with prolapse.

In commenting upon the visual results it will probably strike many as singular that 20-20 was obtained only four times, but this may be explained by the fact that discission was performed only ten times, and that in quite a number of cases the writer made no test of the vision.

In all of the operations the incision was made well within the limbus of the cornea, and still a little further in at the top of the incision. The latter includes usually something less than half the circumference of the cornea.

The instruments, with the exception of the knife, are boiled. The knife is allowed to remain in Squibb's absolute alcohol for twenty minutes. The eyebrows and that side of the face are covered with a cloth saturated with a solution of sublimate 1:1000. Both the cocaine and atropine solutions are boiled in test tubes and only used once. Small pledgets of cotton secured by sponge-holders and boiled are used for removing débris from the field of operation, such, for instance, as strings of mucus and small clots of blood. The unoperated eye is closed till the second day, and a small pad of sterilized absorbent cotton is placed over the operated eye and over this a four-tailed bandage. The eye is inspected on the second day, and earlier if there be unusual pain. The room is darkened, but is not uncomfortably dark. The patient is allowed to get up on the second day, and the bandage is removed on the seventh day, though there was a time when the author removed it earlier.

#### THE SURGICAL TREATMENT OF WANDERING SPLEEN.

STIERLIN (*Deutsche Zeitschrift für Chirurgie*, 45 bd., 3 and 4 heft, 1897) contributes the history of a case of wandering spleen which was treated by coelio-splenectomy. The patient was thirty years old and suffered from typhoid fever and malaria. The latter condition lasted intermittently for two years and left her with a hard swelling under the left costal border which pained her upon walking. After each pregnancy she noted the swelling became increased; massage also seemed to stimulate this growth. On examination it was about the size of a man's head, was movable, and resting on the symphysis. It appeared to lie immediately beneath the skin and presented a notch. It was extremely movable. A median incision was made from the navel outward. The spleen was readily delivered through a comparatively small wound. The pedicle, about eight inches wide, was, after isolation and ligature of the main artery and vein, seized in forceps, divided, and ligated by two rows of lock ligatures. During operation the patient's condition was very good. Immediately on removal of the spleen there was marked weakening of the pulse. This was transitory, however, the heart again regaining its normal tonus promptly. Twenty-two hours after operation the patient was found

in complete collapse, with thready, uncountable pulse, Hippocratic countenance, and dry, crusted tongue. A liter of salt solution was injected into the rectum, and this was repeated twice during the day. The patient gradually reacted and the following day was in good condition. Two days later vomiting began. Repeated enemata were ineffectual in moving the bowel, and meteorism became pronounced. The next day a large dose of castor oil was given by the mouth. At the same time the same drug was administered by enemata. This treatment was efficient; vomiting and meteorism immediately disappeared, the temperature rose the same evening and remained up for over a week. This patient reported a year later apparently perfectly well, excepting for a retroflexed uterus which caused constipation, and which she wished remedied. This wish was gratified.

The author observes that since wandering spleen is usually one of the symptoms in splachnoptosis, with but few exceptions it is noted in women. The affection is, however, comparatively rare, Huber having failed to note it in a single one of his twenty-eight cases of enteroptosis.

It is probable that the spleen has little tendency to wander in enteroptosis, unless it is enlarged.

The diagnosis of the affection is easy when the organ is accessible to palpation, since the incisura is almost unmistakable. Under other circumstances the nature of the affection cannot be determined without operation, as when the organ lies deeply it is readily confounded with wandering kidney, or when peritonitis, or at least meteorismal tenderness, develops in consequence of twisting the pedicle.

#### THE INFECTIOUSNESS OF CHRONIC URETHRITIS.

The *Johns Hopkins Hospital Bulletin* for October, 1897, contains an interesting paper on this subject by E. R. OWINGS. In conclusion the writer presents the following propositions:

In many cases of chronic urethritis we are unable to demonstrate the presence of the gonococcus; these cases are probably non-infectious.

In any case the possibility of infection as compared to an acute urethritis is small.

A urethritis due to an attenuated organism, and consequently modified in intensity, may be contracted from a chronic urethritis.

Conversely:

Several negative examinations of the secretion from a chronic urethritis do not prove its non-infectiousness.

The infectiousness or non-infectiousness of a chronic urethritis can only be determined by frequent and careful examinations of the secretion, and if these prove negative, by the non-appearance of the gonococcus after the application of Neisser's test (an acute urethritis caused by saline nitrate injections).

#### INTESTINAL SUTURING.

KUZMIK (*Deutsche Zeitschrift für Chirurgie*, 45 bd., 3 and 4 heft), after a lengthy discussion of the various methods of intestinal suture, completes his paper with the following conclusions: Solution of continuity of intestinal tract, however it may be caused, is preferably restored by suture, the best being the Czerny-Lembert, the Kummer, and when speed is an important element the Maunsell-Ullmann.

When it is imperative that the operation should be completed at the earliest possible moment the Murphy button and direct suture are preferable. The Murphy button should always be reinforced by the Lembert suture. When gastro- or entero-anastomosis are required Senn's method is to be commended, but the opening must be a very large one. Every intestinal suture should be so applied that the mesentery is not separated from the gut; the Czerny-Lembert suture is probably the most popular method. This consists in a first row of sutures including all the coats of the bowel excepting the mucous, and approximating the divided edges. This line of sutures is then turned in by a second row, including all but the mucous coat of the gut, but passing in and out on one side of the wound, across it, and in and out on the other side.

Kummer applies the first row of sutures to the mucous and submucous tissues, approximating the cut edges; the second row takes in the muscular and serous coats. Before attempting suture, the mucous membrane together with its fibrous base is separated from the outer coats for from half an inch to two inches. The mucous membrane is then united by direct suture after its ends have been resected, and the outer tube, made up of the muscular and serous coats, is brought together by what is practically a Lembert suture.

The particular advantages claimed for this operation were the avoidance of cicatricial contraction because of the accurate union of the mucous coat and the assurance against the needle penetrating into the lumen of the bowel in the application of the outer layer of Lembert sutures.

The Maunsell-Ullmann operation, commonly known as the Maunsell, consists in uniting the divided ends of the bowel by four sutures passed through all of the coats. These sutures are placed one at the mesenteric attachment, one at the convex border, and the remainder at the sides midway between these two. The upper bowel loop is then opened about two inches above the seat of section by a two- to three-inch incision placed on the surface furthest removed from the mesentery. Through this opening four threads uniting the cut ends are drawn by pulling upon them; the seat of suture is delivered through this longitudinal opening. Threads are then passed, making a complete ring of sutures, are knotted, and the bowel is drawn back again to its normal position. The longitudinal wound is then closed by the Lembert suture, and the seat of transverse suture is also reinforced by a line of Lembert sutures.

---

*SUCCESS OF DITTEL'S ELASTIC LIGATURE FOR HEMORRHOIDAL NODULES.*

Recovery followed in every one of the 269 cases that have been treated in Dittel's service; twelve days was the average time. No anesthesia is used except Schleich's local infiltration. The curved polypus forceps are guided by a finger of the left hand inserted into the rectum. By turning the forceps ninety degrees the nodule is brought up out of the anus and with the surrounding mucosa is then ligated with an elastic cord stretched to its utmost. The nodules lose their vitality in eight to ten days and drop off, leaving a clean granulating surface. The external anal skin must not be included in the ligature, as this is very painful.—*Journal of the American Medical Association*, Nov. 6, 1897.

*WHAT CAN BE ACCOMPLISHED BY TREATMENT OF EUSTACHIAN TUBE, WITH SPECIAL CONSIDERATION OF THE TREATMENT OF CHRONIC STENOSIS.*

GEORGE MORLEY MARSHALL (*University Medical Magazine*, November, 1897) in a

paper on this topic briefly recalls the anatomy and function of the Eustachian tube, in so far as they concern the measures advocated in this paper. The Eustachian tube is the passage between the naso-pharynx and tympanic cavity—in length thirty-three to forty millimeters. From its relatively large pharyngeal mouth it extends twenty-five millimeters, with walls formed by an incomplete furrow of fibro-cartilage, consisting of a posterior and anterior plate, the anterior being a movable one. This portion of the tube, where not cartilaginous, is membranous, which, with its lining mucous membrane, has considerable thickness. This cartilaginous portion of the tube unites with the remaining ten to fifteen millimeters of the osseous portion of the tube. At this angle the lumen of the tube is smallest—that is, two to three millimeters.

The walls of the Eustachian tube are lined by glandular mucous membrane, with ciliated cylindrical epithelia, whose ciliary movement is directed towards the pharyngeal opening, which has a lower level than the tympanic opening. The lining of the osseous portion is smooth and closely incorporated with the periosteum. With surrounding conditions normal, the normal Eustachian tube allows the passage of air, not with absolute freedom, for the tube at rest has its sides in contact, but with sufficient freedom to establish an approximate equality of atmospheric equilibrium, allowing the secretions of lining membrane of the tube and of the tympanum to escape or evaporate. But if atmospheric pressure is not approximately equal, the air in the tympanum is absorbed by surrounding liquids through the walls of blood- and lymph vessels, obeying the law that liquids absorb their own volume of associated gas, and thus, the air not being renewed in the tympanum, there follow the well known symptoms—deafness, feeling of fullness, a probable tinnitus, autophonia, but especially that decisive sign of present or former obstruction, the appearance of the retracted tympanic membrane itself.

But with retracted membrane the alert aurist would not jump to the conclusion necessarily of an obstructive Eustachian tube, as turgescence or hypertrophy of the turbinated bodies alone might account for the rarefied air to a considerable degree. Still more will the pressure be out of equilibrium if the opening between pharynx and naso-pharynx be occluded.

We must believe that many cases of lesser

degree of obstruction at this point (the nasopharyngeal opening) would still have the effect of disturbing the equilibrium of atmospheric pressure in the tympanum, and the above cases are only cited because of the absolute demonstration of the effect of rarefied air in the naso-pharynx. Other lesser obstructions, as adenoid growths, which the author believes directly arise from a previous nasal obstruction, although possibly a temporary one, and which, producing this rarefied condition of atmospheric pressure, will, with its continuous yet slight suction power, so affect the yielding tissues of the infant as to cause venous congestion favorable to the growth of adenoid tissue. Thus he believes adenoid tissue, instead of being responsible for venous congestion, as is maintained by prominent authorities, is itself one of the sequelæ of the congestion.

Although certainly the continued presence of lymphoid growths favors also the continued congestion and obstruction, so likewise hypertrophies of the turbinated bodies, deflected septi, nasal polypi and nasal spurs may interfere with the ingress and egress of air, and therefore the resulting equilibrium of atmospheric pressure, and they must therefore be removed by appropriate operation or treatment before attention is directed exclusively to the Eustachian tube itself.

Now, if obstruction of nasal passages or nasal pharynx produces this want of equilibrium in the tympanum, so much more will stenosis or occlusion of the tube itself, and this will lead to that venous congestion of the tympanum which the writer believes is responsible for a very large majority of cases of chronic tinnitus aurium, as well as chronic deafness resulting from sclerosis of tympanic membrane and associated structures, for not only is the circulation of the blood abnormal, but the reverberating sound-waves of the blood-currents have no longer their normal exit, but are as in the closed sea-shell which confines the sound in unbroken walls. This tinnitus has been removed for several days after the relief of the venous congestion following the removal of a nasal spur with free hemorrhage, and so is explained the relief after depletive measures, as by cathartics and pilocarpine, which give temporary relief. But the belief that free ingress of air into the tympanum will at last relieve the congestion, and therefore the tinnitus, has been borne upon the writer, especially during the last two years, by the results of a more systematic bougieing of the Eustachian tube,

where stenosis of tube or retraction of tympanic membrane existed. Marshall has a tabulated series of thirty cases which had long become chronic, and which will therefore be of more interest because of the usually intractable nature of such cases. Seventeen were chronic cases of tinnitus, and all chronically deaf, with one exception, which, although a marked case of chronic tinnitus, exhibited no degree of diminished hearing, yet was the first stage of venous congestion. After systematic bougieing, the results in these seventeen cases were as follows: Seven were made entirely free, five improved to such a degree that it became no longer troublesome, while in the other five there was no reported change. But with one exception those who did not improve had but few treatments. In two of the favorable cases, although the tinnitus had been constant for six or more years, it was removed only after six months of treatment. In the twenty-nine cases of chronically deaf, one only was restored to normal hearing, seven were very much improved, five slightly improved, one heard better in one ear, but worse in the other, while in nine there was no change. One of these cases was of deafness without tinnitus, which was decidedly improved by the bougie, although the air douche had previously failed to relieve to the same extent; yet in this case there was relapse to nearly the first condition, although bougied for quite a year. But in no case was there an unfavorable result, unless it was in one case who, six weeks after her last treatment, was taken with an acute middle-ear trouble, which soon subsided; but the patient had been in the interval perfectly free from pain—in fact, relieved in a degree from deafness—and she attributed the inflammation to a severe cold, quite independent of bougieing.

The writer speaks of this as a possible sequel, as he has been particularly watchful for any possible bad effects of the bougieing. Thirty may seem too small a number from which to draw sweeping conclusions, yet the good results in these few cases may have been due to the method used in its performance, and he therefore states his method in the form of rules, which are upon selection of cases, viz., those with retracted membrane and which receive temporary relief by the air douche or massage. His conclusions are as follows:

Never delegate the work to another.

Never do it hurriedly, but always count upon having, if necessary, one-half hour for

the operation. Usually it may be done in a minute or less, but difficult cases arise; if done leisurely it is surprising how easily an apparently difficult case becomes.

Have properly fitting, well-shaped Eustachian catheters. Those from Reiner, in Vienna, have given Marshall perfect satisfaction during ten years of constantly making use of Eustachian catheters.

Have surgically clean catheters and bougies.

Prepare the mucous membrane of nasal passages, especially the pharyngeal mouth of the Eustachian tube, with an application of a ten-per-cent. solution of cocaine.

Smear the bougie with a three-per-cent. ointment made with lanolin and nitrate of silver. This is the measure that is original with the author, and it is to this measure he attributes largely the good results. Unlike other fats lanolin clings tenaciously to the bougie; it shields the bougie and makes its passage more easy; and with the silver nitrate it is antiseptic and locally alterative in effect. He has it prepared from the aqueous solution of silver nitrate, so that it virtually becomes a stiff emulsion. It is only after long exposure that the surface of the ointment undergoes a chemical change, becoming black on the surface, but apparently unchanged beneath.

His seventh rule is to observe that the bougies are in perfect condition. It is possible for celluloid to become brittle and therefore highly dangerous, and for whalebone to become rough or thready, and therefore irritating.

Let the bougie rest in place twenty minutes to half an hour in the Eustachian tube.

Bougie not oftener than twice per week, and

Measure the bougie and see that it does not advance more than thirty-three millimeters.

After making sure of nasal and nasopharyngeal freedom, the above treatment seems to be a rational one, and to be directed at once to the securing of equilibrium of atmospheric pressure in the tympanum; to secure this condition should be the foundation effort. Where equilibrium is wanting, air douching, either by catheter or Politzer's method, or otherwise, as also massage of the ossicles and membranes, can be but of temporary effect.

The analogy of chronic stenosis of the tear-duct and of the male urethra, while not perfect, is at least sufficiently suggestive. It

would be a timid surgeon that in stenosis of either of those passages would rely upon an application of a vapor or a liquid. If gradual dilatation in those passages is indicated and an accepted measure, so likewise is it indicated in the Eustachian tube. That stenosis may at some time return is no argument in any case that the treatment should not be adopted, and yet, because of the delicate nature of the Eustachian tube, it should never be treated by careless or unskilled hands.

A method of treatment in tinnitus aurium, even in so small a series as this, which results in forty-one per cent. of cures and in seventy per cent. of complete relief, is so vastly superior to any method the writer knows of that he states he shall continue it with confidence, although a succeeding and longer series may not give as fair a result.

---

#### HERNIA OF THE BLADDER.

HERMES (*Deutsche Zeitschrift für Chirurgie*, 45 bd., 3 u. 4 heft) calls attention to the rarity of this affection. He states that Sala in 1520 was the first to discover it. The first elaborate and careful study of the pathological conditions was contributed by Verdier in the middle of the eighteenth century.

Aue, in the thirty-ninth volume of the *Zeitschrift*, collected all the cases to the year 1890. The author has continued this collection to the present date. He gives the histories of four cases observed in the hospital. The affection was most frequently observed between the fifteenth and sixteenth years. Only one instance is reported under the fifteenth year; this occurred in the case of a five-year-old child. In the latter case the hernia developed as a sequel to an unsuccessful attempt at a radical cure of an ordinary intestinal hernia. Three cases were observed between the twentieth and thirtieth years, fifteen between the thirtieth and fortieth, eight between the fortieth and fiftieth, nine between the fiftieth and sixtieth, nine between the sixtieth and seventieth, and two after the seventieth year. In forty-seven cases the hernia was inguinal, in eleven crural. As to sex, forty-two inguinal hernias and one crural hernia occurred in males, while five inguinal and ten crural hernias occurred in females. Perineal and obturator hernias recorded in Aue's statistics, respectively eight and three times, are not represented in the latter list, nor are hernia of

the linea alba (Aue, two) nor ischiatic hernias (Aue, one).

The diagnosis of vesical hernia was made before operation in three instances. In thirteen cases it was recognized in the course of operation, and the bladder was therefore not wounded. In twenty-five cases it was wounded during operation and was recognized through this fact, the wound being closed at once. In fifteen cases the wound inflicted during the operation was not recognized, but was later known to have occurred through symptoms which developed.

When the bladder was wounded during operation, it was taken for the hernial sac in six cases; for a second hernial sac in five cases; for a greatly thickened sac in one case; for a subserous lipoma with diffuse masses of fat in four cases; for a second hernia in one case; for omentum in one case; for a cyst in one case. Of the fifty-eight cases collected the bladder was wounded in forty; by ligature sixteen times, by incision seventeen times, in the course of blunt dissection five times, by traction with forceps once. In nineteen cases the bladder was immediately sutured, once after two hours, four times after twenty-four to forty-eight hours; was sewed together with the skin opening twice; tamponaded without suture once. In five cases an ordinary fistula developed spontaneously; once hematuria indicated a wound of the bladder; once because of retention the incision had to be reopened, cure taking place by secondary intention without fistula formation. In one instance the ligature was extruded after six weeks, resulting in the formation of a fistula, but one which did not allow urine to escape.

There were eleven fatal cases. In the first the bladder was ligated, together with the hernial sac; the patient died of anuria in twenty-four hours. In the second case death occurred in nineteen days; the bladder wound was recognized at the time of operation and secured to the skin wound because of tight stricture; the patient perished because of gangrenous dysentery. In the third case a gangrenous diverticulum of the bladder was removed and the wound tamponed; death followed from chronic uremia. Demoulin ligated the bladder, but two days later loosened the ligature and sutured the wound; death followed three days later of static pneumonia. Ostermayer ligated and resected a portion of the bladder, but on the next day recognizing this fact sutured the wound; the patient died of anuria. Stim-

son's case died of shock, an extensive resection of the sigmoid flexure having been required. Hartley's case died of shock and hemorrhage. Ssalistschew, mistaking the bladder for subserous fat, wounded it; he immediately sutured this wound. Death occurred on the third day from hemorrhagic peritonitis, with retroperitoneal infiltration of blood. Prjanischnikow tore the bladder in the course of a blunt dissection, and since he could not suture it made a suprapubic fistula; death occurred in three days from peritonitis and suppuration of the prevesical space. Finkelstein tied the bladder and the omentum; death occurred in twenty-four hours with edema of the lungs and urine in the abdominal cavity.

It has already been mentioned that in only three instances was the diagnosis of vesical hernia made before operation. None the less the diagnosis of this affection is comparatively easy. There is usually some disturbance in the complete evacuation of the bladder. This is difficult; the patient is often required to take a certain position before he can empty his viscus, or it may be necessary for him to press with his hand in the region of the hernia. There is often pain, and the urine can be evacuated only drop by drop; sometimes there is retention. Sometimes the bladder can be emptied only after two efforts: the first, evacuating the urine in a portion of the bladder which is normally placed; the last, from the portion of the viscus which forms a part of the hernia. The bulk of the hernia varies in accordance with the fulness of the bladder. Frequently the surgeon will feel in the external ring a soft, round, fluctuating tumor, usually irreducible, which remains when the rest of the hernia has completely disappeared. The passage of a catheter or fluid into the bladder will prove the connection between this tumor and the vesical reservoir. The sound, if it is solid, is often turned toward the side on which the hernia exists. Often there are only one or two characteristic symptoms, or they may all be absent. Statistical study shows that during the operation hernia of the bladder will lie in the inner lower portion of the hernia, covered with a layer of fat. The color is either that of fat or lemon-yellow, sometimes gray-yellow. This layer of fat is intimately united with the hernial sac so that the separation of the two by blunt dissection is often impossible. In the course of such a dissection in some cases the retiform arrangement of the muscles of the bladder has been

demonstrated. Usually the introduction of a catheter into the bladder at once demonstrates that this mass, forming a part of the hernia, is a portion of the vesical wall. Moreover, on following the base of this tumor with the finger the latter is always directed behind the pubis. The prevesical layer of fat seems to be always well developed in cases of vesical hernia, forming almost a true lipoma. Furthermore it is held that this is really the cause of the bladder hernia. In thirty-eight of the fifty-eight cases this lipomatous formation on the inner border of the inguinal canal was observed.

When every diagnostic sign fails during the course of an operation, the surgeon should open the abdomen above, and thus he is enabled at once to assure himself whether or not the bladder forms part of the hernia.

The three forms of bladder hernia are the intraperitoneal, extraperitoneal, and the partly intra- and partly extraperitoneal. The first form is extremely rare; the last form is extremely frequent, and especially in later years because of the popularity of the radical cure of hernia. Thus in this operation the sac is tied as high up as possible, the peritoneum being well pulled out when the ligature is applied. It is readily seen how this may draw upon the bladder, pulling this viscus toward the seat of ligation, and thus paving the way for subsequent hernia. In Hermes' collection there was only one instance of pure intraperitoneal vesical hernia. This formed a projecting tumor on the inner side of the hernial orifice, which on examination was found to be continuous with the bladder.

The vesical hernia can only be treated by radical operation. A truss can be of little service since these hernias are always irreducible, hence pressure is liable to irritate, to make adhesions more dense, and favor cystitis. It has usually been found that the application of a truss distinctly aggravates the patient's suffering. If the bladder is recognized in the hernial contents it should be mobilized and replaced, radical operation for hernia then being completed in the ordinary manner. The result is completely satisfactory. The freeing of the bladder is best accomplished by blunt dissection, but it will often happen that the knife and scissors must also be employed. The prevesical lipoma or the diffuse layer of fat overlying the bladder should be removed. This method is much better than that recommended by

Monod—*i.e.*, resection of the prolapsed portion of the bladder. If the prolapsed portion shows signs of gangrene it should be resected. If the resection has been carried through sound tissues and there is not a very aggravated cystitis, the bladder should be closed by sutures, the wounds of the soft parts then being treated by tamponade. After the bladder is firmly closed the operation for radical cure of hernia can be completed. In unfavorable cases it is probably wise not to attempt suture but to provide for drainage.

When the bladder is accidentally wounded in the course of operation it should receive immediate attention. The opening should be closed by suture, thin and diseased parts being cut away so that the threads may be carried through sound tissue. It is noteworthy that satisfactory results have followed every method of suture, provided the threads have been passed through comparatively sound tissue. The idea would undoubtedly be to replace the bladder after suture and complete the radical operation for hernia and close the wound without drainage. In three instances has this procedure been followed, and with entire success. Tamponade, reserving the cure of hernia for subsequent operation, seems safer, however. If the wound of the bladder is recognized only after completion of the operation—*i.e.*, in the hours or in the day following—the wound should be opened and secondary suture applied. *Fistulæ* which result from drainage usually close spontaneously.

To this admirable paper Hermes appends histories of fifty-eight cases.

---

#### KOCH'S NEW TUBERCULIN.

At a meeting of the Medical Section of the "Niederrheinische Gesellschaft fuer Natur- und Heilkunde," held July 12, Prof. Dr. Doutrelepon reported his experience in the employment of Koch's new tuberculin. Experiments thus far made testify to the favorable action of Tuberculin R. upon lupus. In all cases under observation progressive improvement was visible as a result of the injections; final judgment cannot yet, however, be rendered. Emphasis should be laid upon the fact that in every case in which resort is made to higher doses the quantity should not be rapidly increased, in order to avoid provoking marked fever, which harasses the patient.

From the medical clinic of the University of Greifswald Dr. Bruno Leich states: "Experiments thus far made afford no secure ground for assuming that the T. R. is capable of specifically and favorably influencing the tuberculous process."

From the medical department of the Allgemeines Krankenhaus in Hamburg-Eppendorf, Dr. de la Carp reports a clinical lecture by Dr. Rumpf. The latter concludes that the preparation T. R., in view of its reaction, or rather non-reaction, is not a constant and reliable preparation, inasmuch as minimum doses often produce fever, while larger doses may sometimes be borne by the same patient without any disturbance. It is very doubtful whether immunity from tuberculosis is produced by the maximum dose recommended by Koch. Only at the very outset in the treatment of incipient and restricted tuberculous processes of the lung can a careful test be made with T. R.; but a uniformly active preparation should be furnished by the factory.

From the otological department of the Charité Hospital in Berlin Dr. Richard Mueller comes to the conclusion that the influence of the new tuberculin upon the ear is not a favorable one.

In laryngeal tuberculosis Dr. J. Herzfeld has used T. R. considerably. It would be idle to talk of favorable results following the treatment of laryngeal tuberculosis in the cases coming under his observation. Local treatment would certainly have yielded better results, and it cannot be dispensed with even when the injection cure is applied.

From the Sanatorium at Schomberg Dr. Baudach reports twelve cases. He believes that his experiments were on the whole of decided benefit, and that the treatment undoubtedly accelerated in several cases the progress of the improvement previously established; a general hygienic and dietetic treatment and the open air cure supplemented the tuberculin.

Dr. Roszmann, of Brunswick, observed a violent reaction to an injection of T. R. in a female patient; fever lasted for twenty-four hours; pulse 120 to 180; digestion disturbed; general prostration persisted for several days, and headache.

In the Paris Biological Society Professor Maragliano reports his experiments. He injected the T. R. into three tuberculous patients, and one non-tuberculous patient. Fever or exacerbation of fever ensued in all; the rise in temperature persisted for two to

four days. In tuberculous subjects the injection seemed to provoke physical disturbance in parts of the lung where none existed before. In healthy guinea-pigs as well as in tuberculous pigs the temperature was increased by the injection. Using equal doses of the old and new tuberculin, the healthy and diseased animals both showed the same reaction. Microscopical examination of the turbid preparation showed bacteria and yeast germs. It would accordingly seem that there is no difference between the old and new preparations, save that the new preparation seemed to be worse than its predecessor.

Dr. Bouchard terms the new tuberculin "an impure bacteria-infected product, entirely unsuited to scientific investigations."

At Paris the house has requested permission to undertake the sale of Koch's tuberculin. In passing upon this petition the Minister of the Interior applied to the Paris Academy of Medicine. Dr. Nocard, who stands at the head of the Serum Commission, instituted an investigation of the product and reports as follows:

"The preparation in question is one manufactured abroad. Its production is of such a nature that an examination on the spot of the details of manufacture is impossible. It is moreover not possible at the present time to obtain specimens for the purpose of undertaking researches of the specific properties ascribed to the preparation by its discoverer. Investigation on the spot, however, and subsequent examination are demanded of similar French institutions. The accompanying specimen, one cubic centimeter, is altogether too small to permit experimental or clinical tests; moreover the statements made by Koch, and in accordance with which the preparation is manufactured, are too meagre in detail to convince the reader of the harmlessness and activity of the new tuberculin. The Academy would like to postpone its pronouncement until clinical experience or at least experimental tests corroborate the statements of the author. Such tests might last for several months. But the scientific importance of Koch and the natural impatience of the sufferers constitute peculiar factors which render impossible a longer delay. Therefore the Serum Commission would make an exception, and for this purpose it asks the permission of the Academy to express a preliminary report which is to receive later on a definitive sanction. The quantity of material necessary for these investigations should be placed by the manufacturers or importers at the dis-

posal of the Serum Commission. It must further be demanded that the tuberculin introduced into France shall be perfectly aseptic. This demand seems to be necessary, for *all samples of the new product which have thus far been investigated were turbid, and the microscopic examination showed bacteria to be present in great numbers.* These bacteria did not seem to be of pathogenic nature, but the possible intrusion of pathogenic germs is not excluded. Moreover, the harmless microbes may paralyze the active substance of the preparation. Accordingly, the new tuberculin should be granted free sale by the French authorities when experimental and clinical tests have established its harmlessness and efficacy. Until that time the introduction of the preparation into France should be granted temporarily, and its sale be permitted under the condition that it be perfectly aseptic."

CUTANEOUS MEDICINE. A Systematic Treatise upon Diseases of the Skin. By Louis A. Duhring, M.D. Illustrated.

Philadelphia: The J. B. Lippincott Company, 1898.

This, the second, part of Dr. Duhring's new work appears so long after Part I, with which its pages are continuous, that some of our readers doubtless forget that this well known author is engaged in the rewriting of his book on Skin Diseases. The present portion, which is published as a separate volume, although its first page is 223, begins with the classification of skin diseases, describes the various classifications which have been designed by different dermatologists and that which Dr. Duhring himself has instituted. In regard to special diseases, we find that in class one he discusses the anemias, then the hyperemias, including the various forms of erythemas; and in class three the exudations and inflammations. In each instance the text deals with the various forms of the disease, its pathology, etiology, and treatment, and very frequently full-page illustrations, often made from original observations of the author, and water-color sketches illustrate the text. When it is remembered that these illustrations are not colored and yet give clear ideas of the pathological conditions of the skin which they are designed to represent, it will be recognized that the cases from which the pictures were taken must have been most typical, the artistic work excellent, and the labor of the photo engraver of the best.

In the article upon Urticaria Pigmentosa the dermatologist has written across the back of his patient "Urticaria Pigmentosa" with some small instrument, and the wheals have appeared in the skin so that the words appear clearly in the photograph. The important subject of Eczema takes up a large amount of space, as is natural and proper, and there are other chapters upon Impetigo, Ecthyma, Pemphigus, Pompholyx, and the various forms of Herpes, an article upon Herpes Zoster closing the volume.

It goes without saying that anything written by Dr. Duhring upon the subject of Diseases of the Skin commands at once the attention of both the specialist and the general practitioner, and for this reason, and because of the very evident worth of the volume, we earnestly commend it to the readers of the GAZETTE, expressing the hope that the author will see his way clear towards bringing out the subsequent volumes, which will complete the work, more rapidly than the first and second, which we have noticed in our review columns.

THE PRINCIPLES OF BACTERIOLOGY. A Practical Manual for Students and Physicians. By A. C. Abbott, M.D. Fourth Edition, enlarged and thoroughly revised. Price, \$2.75.

Philadelphia and New York: Lea Brothers & Co.

It is not often that a book devoted to a special subject, not intimately connected with the practise of medicine, is so appreciated by the profession as to run through edition after edition in the manner in which Dr. Abbott's has done. In the preface to this edition the author acknowledges, with thanks, suggestions which have been sent to him by readers who have been competent to make them, and he has embodied the more important of the newer ideas bearing directly upon the subjects under treatment. Illustrations of the bacillus of bubonic plague, influenza, of the micrococcus of gonorrhea, and a number of others relating to descriptive passages in the text, have been added.

Those who are familiar with Dr. Abbott's book know full well that one of its most attractive characteristics is that it enables the student, or medical practitioner, to pass from theme to theme or experiment to experiment in sequence, and that the directions are so clearly given that any one with a moderate amount of laboratory training can, with a little care as to detail, make his experiments successfully. To the practitioner who is unable to carry out bacteriological studies for himself the twenty-sixth chapter upon

infection and immunity will perhaps be the most interesting in the volume, for in this we have a brief and able summary of these very important subjects which are pressing so closely upon the attention of progressive medical men.

The volume closes with a description of the methods employed in the bacteriological examination of water and the methods of testing disinfectants. In an appendix we find a description of the microscope and the necessary accessories which are required by any one who desires to use the volume as a handbook in the laboratory. We doubt not that Dr. Abbott's fourth edition will prove even more popular than its predecessors, and to those who require a small and condensed yet nevertheless complete work upon Bacteriology, we most cordially recommend it.

THE TWENTIETH CENTURY PRACTICE OF MEDICINE.  
Volume XII: Mental Diseases, Childhood and Old Age.

New York: William Wood & Company, 1897.

Although this volume deals with subjects that are not of particular interest to the general practitioner, it is nevertheless one of the best which has appeared in the series, not only because its contributors are men well known as specialists in the subjects of which they write, but also because their literary productions in almost every instance not only maintain but increase our respect for them as authorities.

The first article of this volume upon Insanity is by Dr. G. Fielding Blandford, of London. After devoting a very few pages to the Cerebral Anatomy, he passes on to the pathology and etiology of insanity and its predisposing causes, and in this chapter brings forward many interesting points in regard to this important subject, advancing the idea with strong endorsement that the vices of Western nations combined with the development of civilization very gravely increases the frequency of mental disorders. As an illustration of this he quotes some statistics by Dr. Bucke, who in 1880 found that the proportion of insane to healthy persons amongst the white population was one in 500, while the proportion among negroes was one in 1100. Under the head of Exciting Causes of Insanity he discusses insanity from overstrain, and from such physical causes as epilepsy and alcoholism, and the insanities which result from the various poisons such as syphilis, rheumatism, gout. Many other so-called exciting causes of insanity are also discussed, a consideration of the morbid

anatomy and the symptoms of insanity follows, and then he considers the various forms of insanity as recognized by neurologists. Altogether this very able article of Dr. Blandford extends over 253 pages and has a considerable bibliography appended to it. The article upon Idiocy by Paul Sollier, of Paris, amounts to 114 pages and is quite exhaustive; while that upon Criminal Anthropology by Cesare Lombroso, of Turin, is of about fifty pages. This author has written so largely upon this subject that one turns to his article with considerable interest, although, of course, it cannot be considered a distinctly medical one. Lombroso differs from Crichton and Spitzka, who confound born criminals with paranoiacs, who among other differences frequently exhibit exaggerated altruism, and rarely the degenerative stigmata of criminals. An interesting conclusion to his chapter is that devoted to the therapeutics of crime.

The article on Old Age, by Boy-Tiessier, of Marseilles, is 106 pages in length and deals with the general subjects of the anatomical and pathological changes of senility, the diathetic causes of premature old age, natural death, and the susceptibility to senile changes of various organs. The last part of the volume, extending from page 534 to 831, is filled with a very interesting article by Comby, of Paris, who discusses the diseases of children in what amounts to a small textbook upon this subject. Naturally much of the information given here is limited in its scope, but nevertheless it forms not the least valuable portion of Volume XII. We are glad to notice that Professor Comby has included in his article full directions in regard to the treatment of the diseases of which he writes.

A TEXT-BOOK OF NERVOUS DISEASES. By Charles L. Dana, A.M., M.D., New York. Fourth Revised Edition.

New York: William Wood & Company, 1897.

Medical books, like works in the realm of general literature, can be and are divided into three great classes: The first class are those which from their first appearance from the press are failures; the second class is composed of that somewhat smaller division, the books of limited popularity and value; while the third class is that represented by the books which spring at once into well deserved usefulness and popularity. It is to the latter class that Dr. Dana's volume belongs. The valued work of the author in general neurological literature, combined with the faithful pictures of nervous disease

which he has drawn for his book, have produced a manual which, good at first, has steadily improved instead of decreasing in value by careless revision. In the present edition the part on peripheral neuroses is entirely rearranged; new chapters have been added on encephalitis, multiple sclerosis, meningitis, and traumatic neuroses. The anatomical chapters have all been revised and rewritten, and the anatomy and pathology of the work have been brought into relation with modern views as to the neuron architecture of the nervous system. The therapeutical part has been extended by additions to the appendix, giving technical details of the various accepted therapeutic measures of modern neurology.

**THE MEDICAL NEWS VISITING LIST FOR 1898.**

Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). Seal grain leather. Price, \$1.25; Thumb-letter Index, 25 cents extra.

Philadelphia and New York: Lea Brothers & Co., 1898.

This Visiting List is too well known to our readers to require much description. It will be remembered that the early pages of it contain condensed information in regard to the date of confinement, conversion of thermometric scales, weights and measures, examination of the urine, and a table of the date of eruptive fevers, a description of the common poisons and their antidotes, and a table of doses, with a therapeutic reminder following it. Finally, and perhaps most valuable to the physician in an emergency, is a four-page summary describing the ligation of arteries and accompanied by a full-page figure showing where the incisions are to be made for the performance of these ligations. It can be cordially recommended as a ready aid to the physician in keeping a record of his visits and of his general and special practise.

**VADE MECUM OF OPHTHALMOLOGICAL THERAPEUTICS.**

By Dr. Landolt and Dr. Gygas.

Philadelphia: J. B. Lippincott Company, 1898.

The "busy practitioner" and the "student preparing for examination"—that convenient duo at whose feet so many literary libations have been poured—are the beneficiaries of the present somewhat diminutive compilation which has been prepared, so the rather labored "Introductory" informs us, to give them "a constant companion and a true friend." The book is composed of an alphabetical list of diseases commonly encountered

in ophthalmic practise and of the remedies which experience has taught are suited to their amelioration. The reader is impressed with the fact that the writers believe in the efficacy of drugs, and this faith is as refreshing as the "pillow of hops" will be, we trust, which is advised for the relief of insomnia's victims. A goodly number of very useful formulas have been gathered between the covers of this small book, and the reputation of the authors is a sufficient guarantee that the therapeutic recommendations are sound.

**A MANUAL OF PATHOLOGY, INCLUDING BACTERIOLOGY, THE TECHNIQUE OF POST-MORTEMS, AND THE METHODS OF PATHOLOGICAL RESEARCH.** By W. M. L. Coplin, M.D. Freely illustrated.

Philadelphia: P. Blakiston, Son & Company, 1897.

In the preface to this volume, which extends over about 650 pages, including the index, we are told by the author that the work is an amplification of the lectures in Pathology, so-called, which were published by Blakiston during the winter of 1894-95. We are also informed that whereas this first edition contained but 250 pages and fifty-one illustrations, the present volume contains 268 illustrations and the number of pages which we have already mentioned. It will therefore be seen that in amplifying his lectures Dr. Coplin has produced a fairly complete manual of the subject of which he treats. Indeed, from the scope of the volume it may be considered a fairly complete work upon pathology, although the author tells us that he has designed it not as a treatise or book of reference, but chiefly as a manual for use in the laboratory, post-mortem room, and in clinical diagnosis by the microscope. The first part deals with technique, and in this part we find chapters upon post-mortem examinations, histological methods, microscopic examination of the urine, sputum examination, and blood examination.

Part II deals with general pathology, and after giving the various definitions which are commonly employed in the discussion of pathological processes he proceeds with chapters describing infiltration and degeneration, neurosis, circulatory disturbances, inflammation and its results, tumors, bacteriology, animal parasites, temperature changes, and intoxications and infections. In the third part devoted to special pathology we have the consideration of the diseases which affect the blood, the serous and mucous membranes, the circulatory and respiratory systems, the glands, the digestive apparatus, and the urinary organs.

The book is printed upon good paper with clear type and heavily leaded, which adds much to its value as a work of reference and study. Careful examination of its pages shows that Dr. Coplin has brought to bear his large experience in the teaching of students, for it is concise, and the facts are stated in language which is not involved. To the students who have the pleasure of listening to Dr. Coplin's lectures the book will undoubtedly prove of very great value, and we firmly believe that the students of other schools will come to rely upon it as one of the best summaries of pathological facts which they can study. Unlike many books upon special subjects the pages of this one are beautified by the insertion of a great many illustrations, many of which are original and are drawn from preparations made from pathological material by the author.

**A MANUAL OF CLINICAL DIAGNOSIS BY MICROSCOPICAL AND CHEMICAL METHODS.** For Students and Practitioners. By Charles E. Simon, M.D. Second Edition, enlarged and revised. Philadelphia and New York: Lea Brothers & Co., 1897.

When the first edition of this book appeared, a little over a year ago, we perceived at once that it was destined to prove a success, because it placed before the reader the practical facts which are needed in practise and avoided some of the intricacies of chemical analysis and microscopical technique which, while necessary in works of other forms, would be cumbersome and useless to the general physician. The training of the author in these fields of clinical medicine was admirable, and he has put it to good use in the preparation of both editions. We can warmly recommend the volume to those who are desirous of having at hand a careful, accurate and complete summary of the means employed in clinical medicine, by the aid of the microscope and other apparatus and reagents, in arriving at a correct and scientific diagnosis of a malady.

**TRAUMATIC INJURIES OF THE BRAIN AND ITS MEMBRANES.** With a Special Study of Pistol-shot Wounds of the Head in Their Medico-legal and Surgical Relations. By Charles Phelps, M.D. With forty-nine illustrations. New York: D. Appleton & Co., 1897.

This work the author states has been based on 500 consecutive cases of recent occurrence. These cases are sufficiently varied in their character and sufficiently complete in histologic and microscopic detail to afford a comprehensive history of intracranial traumatism. The section devoted to

cerebral abscess has been supplemented by abstracts from Macewen's History of the Pyogenic Inflammations of the Brain and Spinal Cord. At the end of the book there is a condensed history of 300 intracranial traumatisms selected from a series of 500 original cases. The lesions caused by pistol-shot wounds of the head have been considered apart. In this section of the work is embodied the results of cadaveric experiments, having for their end the settlement of questions likely to rise in medico-legal testimony. The classification is not different from that commonly found in text-books. The discussion of the various theories of contrecoup is extremely rational.

The first chapter of the book is devoted to pathology, then follow symptomatology and diagnosis, a particularly valuable and practical part of the work. Under treatment the first step after having combated shock is shaving the head, both from a diagnostic and therapeutic standpoint. The general outlines of treatment are laid down in a previous portion of the work, but Phelps states that it is in cases of intracranial lesion without implication of the cranial wall that new problems of treatment arise. This work is one of very great value both to the practitioner and the surgeon, founded as it is upon an extensive experience. Its teachings are neither radical nor dogmatic. The author takes a position of advanced conservatism and discusses this difficult subject with a clear common sense which is refreshing in these days of deductions from the collated statistics of the work of others.

**THE DISEASES OF WOMEN.** A Handbook for Students and Practitioners. By J. Bland Sutton, F.R.C.S. Eng. and Arthur E. Gilles, M.D., B.Sc. Lond., F.R.C.S. Edin. Philadelphia: W. B. Saunders. London: Rebman Publishing Co. 1897.

The authors state that in writing this book they have earnestly desired to place the science and art of gynecology in a way that may be useful to students for examination purposes and which will enable them to practise this department of surgery successfully. When there are so many excellent works on this subject, such as those of Penrose and Baldy, already in the market, the reviewer is at a loss to determine the exact reason for issuing still another. The only advantage that this one possesses is its comparatively small size. It has an excellent index and is well illustrated, as are all Saunders' books, and has been arranged somewhat in the form

of an epitome by judicious use of large type headings. The authors are certainly deserving of credit for the skill with which they have been able to select essentials and to describe the most approved and accepted methods. There can be no doubt that both the student and practitioner who buys this book will find a safe guide.

THE ROLLER BANDAGE: WITH A CHAPTER ON SURGICAL DRESSING. By William Barton Hopkins, M.D. With Illustrations. Fourth Edition. J. B. Lippincott Company, 1897.

This admirable compend, of a size to be readily carried in the coat pocket, is so favorably known that further words of praise are unnecessary. The illustrations are excellent and sufficient, and the work is comprehensive, though the important cross-of-the-perineum should have been inserted. There is a final chapter on Surgical Dressings, and there are some especially valuable practical remarks on the subject of the plaster-of-Paris bandage and its proper application. In this part of the work is an excellent prescription for benzoated collodion and a very ingenious plaster dressing called the splint-spiral.

A PRACTICAL TREATISE ON SEXUAL DISORDERS OF THE MALE AND FEMALE. By Robert W. Taylor, A.M., M.D. With 73 illustrations and eight plates in color and monotone. New York and Philadelphia: Lea Brothers & Co., 1897.

The author states that in this work he has endeavored to describe the anatomy and physiology of the sexual apparatus in a scientific manner, and in so doing to incorporate the results of an extended personal investigation. He has given to urethral inflammations as the underlying causes of sexual impairment their due importance, and in a chapter dealing with chronic affections of the prostate has incorporated much that is new which has been developed by his investigations. He has fully elaborated the conditions of the seminal vesicles and their relation when diseased to sexual disorders, and in the matter of therapeutics has exercised care and moderation in making prominent practical and efficient methods of treatment indicated by pathological causative factors. Sterility in women is considered in a general manner, with the idea of conveying to the mind of the reader the conditions which tend to render a woman infertile, and a description of the various vulvar and vaginal lesions, the result of many years of personal study, is quite fully given in the hope of placing it on a clear and scientific foundation.

The foregoing remarks are taken almost verbatim from the preface of this admirable work, since they describe clearly and concisely the objects aimed at and the scope of the book. It may be said without fear of contention that the outline thus presented is more than realized in the pages which follow, and that this book stands in its own class without a peer. The illustrations are numerous and admirable and, with the exception of seven, are all original. The text is characterized by the force and clearness for which we look in all that comes from the pen of this acknowledged leader.

NOTE ON THE WOUNDED IN NAVAL BATTLES BETWEEN JAPAN AND CHINA DURING 1894-5. With Some Considerations on Sanitary Conditions During the War. Read before the Twelfth International Medical Congress, held at Moscow in 1897, by S. Suzuki, M.R.C.S. Eng., L.R.C.P. Lond., Fleet-Surgeon, Imperial Japanese Navy.

This brochure opens with a brief but comprehensive description of the naval battles of the war and incidentally points out the very slight damage done by the Chinese fire. In the great naval battle of Yalu Japanese ships received more than two hundred shells; the number of persons killed or injured amounted to 298. Then follow the tables giving details of the wounded. The crew of the *Matsushima* suffered most severely, losing nearly twenty-nine per cent. In this vessel it is calculated that nine men were killed or injured for every shell which hit its mark. When the shells burst the damage was always greatest, a single missile having killed thirty persons and injured seventy, half of them owing to the explosion of the gunpowder itself; this was a 30.5-centimeter shell. A missile of the same nature killed and wounded on the *Heiji* forty-one persons; while on board another vessel ten persons were killed or injured by the bursting of a 50-millimeter shell. Little damage was done when the shell perforated without bursting. Fragments of ship planks, etc., caused heavy damage: thus the fragments of the funnel of the *Fuso* struck by a shell killed or injured ten seamen.

Excepting very extensive injuries, such as burns involving the greater part of the surface or laceration of the major part of the body, the number of head wounds was greatest—i.e., over twenty-one per cent. of the total number. Comparing the number of wounds received in the land fight with those of the sea fight they were almost identical. The only marked difference between them is

that in the former case the greatest number of wounds received were those of both extremities, the head wounds coming next, while in the latter cases the head wounds were most numerous, those of both extremities coming next.

Similar statistics are given of the killed or injured during the attack upon Wei Hai Wei. Attention is called to the careful consideration given sanitary regulations in the Navy resulting in the practical eradication of kakai. The number of deaths from disease during the course of the war was 177. The number killed was 150; twenty-four men died of typhoid, 18.2 per cent. of the total number of cases.

This extremely interesting report proves conclusively how thoroughly modernized has become the practise of sanitary science in the Japanese Navy.

### LONDON LETTER.

By RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P.  
LOND.

Two important meetings dealing with matters of hospital reform have been held in the course of the past week. Not the less important was that of the Council of the Hospital Sunday Fund. Having regard to the purely commercial character of the agitation as fostered within the profession, it has long been evident to us that if reform is to come in an acceptable form to all parties, it must be effected by the action of those who hold the purse-strings. At present the Hospital Sunday Fund is the most important paymaster of the hospitals, and to this will shortly be added the Prince of Wales Hospital Fund. If the Committee of Distribution of both these funds can be brought to concerted action, their authority would be so great that none but the richest hospitals could afford to ignore it. On these grounds we welcome the recommendation of the Distribution Committee of the Hospital Sunday Fund that the governors of hospitals shall be advised to appoint inquiry officers or almoners to investigate the fitness of applicants for out-patient relief. This plan has been already adopted at one or more of the large hospitals, and has been found to work admirably, notably at the Royal Free Hospital, with the result that the abuse of charity is

almost a vanishing quantity. Still it is purely suicidal for a single hospital to take isolated action, as the rejected applicants are welcomed at other hospitals, often within a stone's throw. However, the most recent resolution of the Council of the Hospital Sunday Fund will do much to safeguard the interests of such hospitals as make a serious effort to grapple with the whole question. This is to the effect that wherever a hospital having an out-patient department has appointed a special and efficient officer for detecting any abuse in that department, it shall be regarded by the Distribution Committee as an important factor in determining the merits. It seems clear to us that such a method of inquiry should be generally adopted, and once the applicant has passed this official scrutiny, the medical officers of the hospital are absolved of any other duty than therapeutic. The only alternative to a recognized inquiry officer is that the physicians and surgeons of the out-patient departments should constitute themselves relieving officers, and this is intolerable. In London, with a population of over four millions, nearly one-third of this number are in receipt of free medical relief. So far the question seems fairly easy of solution, but the general practitioner has still to be reckoned with. A grotesque proposition was made at the meeting of the Hospital Reform Association by one of their number, that patients should only be admitted to hospitals on the recommendation of medical men; in other words, the hospitals are asked to depend for their clientele on the willingness of the general practitioner to sign away his income. We fear that such a Utopia has yet but a visionary existence, even in the world of general practise. Again, it is urged that trivial cases should not be admitted to the out-patient departments; but we submit that the patient is the best judge of the triviality of his own disorder, and if he be a fit subject for hospital relief he should be allowed ready admission.

The extreme bluntness of Sir Henry Burdett will hardly commend itself to the general practitioner, nor is it true of the bulk of them; but the general practitioner along with the hospital physician has to suffer for the sins of his shady *confrères*. Sir Henry Burdett concludes that the great growth of the out-patient departments shows that in some way or another this has been found in the experience of the multitude the best means of treatment at their disposal. This

conclusion, even if substantially correct, takes no cognizance of the fact that in the one case the treatment is gratuitous, in the other on payment. We do, however, agree with him that in some cases the hospital may be a haven of refuge for the sufferers from the inefficient treatment of the general practitioners, but this is the exception and not, as he assumes, the rule. Much of the outcry is due to the fact that the number of medical men is far in excess of the needs of the community. The general public have begun to awaken to this fact, as may be seen from the all-round drop in the number of entries at the London medical schools for this October session. This cannot be accounted for by the growth of provincial medical schools, but represents the balancing process always occurring in the laws of demand and supply. With some of the smaller hospitals it is becoming a serious question whether they will be able financially to keep their heads above water with the great decrease in the amount of students' fees. Possibly a rearrangement of their topographical distribution might help to solve the question, but removal of a hospital *en masse* is not a matter to be undertaken at a period of financial depression.

Several of the medical journals have recently contained articles and notes on the treatment and causation of incontinence of urine in children. The experience of a large out-patient department at a children's hospital has led one to look with suspicion on the various remedies that from time to time are vaunted as specifics. In the presence of enuresis the budding practitioner seems to think reflexly of belladonna. In our experience it has certainly been of great value in some cases, but we have never been able to define the class of cases in which it is likely to be useful. We strongly agree with Dr. Coult's practise of giving the drug in one large dose at night, and not in smaller doses throughout the day. Another drug from which we have often got good results and sometimes simultaneously is *rhus aromatica*, a drug not much in favor on this side of the Atlantic; not infrequently we have used it in combination with belladonna. Dr. Coult speaks well of the tincture of *lycopodium*, which he gives in doses of twenty drops three times a day to a small child, increasing the amount gradually until a drachm is given. Harry Fenwick prefers a tincture prepared by triturating *lycopodium* with sugar of milk, after which it is readily soluble in alcohol. Bromide has always seemed to us a

two-edged sword, and though often very useful in cases where incontinence is due to nervous hyperexcitability, it is sure to increase the trouble in those very frequent cases in which the lack of control of the vesical sphincter is associated with heavy sleep; then any agent should be avoided that deepens the inertia of the higher centers of nervous control. We have found great value from strychnine in cases of diurnal incontinence, and in some cases of nocturnal type where the condition has been associated with obvious debility; and the latter condition is also a clear indication for the use of iron. A great many cases of nocturnal enuresis have an associated history of rheumatism, but we cannot say that we have observed any good result from the use of salicylates; nor have we been able to satisfy ourselves that this association is marked clinically by an increased acidity of the urine. There is no doubt, however, that enuresis in a number of children is due to a highly concentrated urine irritating the bladder, and that the condition should be met not by diminishing but rather by increasing the fluid intake. In some cases the incontinence has been clearly associated with a definite source of irritation, such as a loaded rectum, threadworms, or a tight or adherent prepuce; and these cases often but not always may be subdued by the removal of the cause. However, whatever remedy we employ in medicine, it is of little use unless backed by precautions as to diet, position in bed, and regulation of micturition. We have succeeded in curing several cases by forbidding the pernicious habit of giving tea to small children to drink at their last meal. In conclusion, we would like to put it on record that not a few cases have come under our notice in which the disorder has followed circumcision—we suppose from exposure of the sensitive glans penis.

Dr. Clifford Beale, in a paper read before the Harveian Society, has reopened the vexed question of the usefulness of creosote in consumption. He had given pure beechwood creosote in cod-liver oil, beginning with 3-5 minims and increasing the dose by the same amount every other day until a maximum dose of 180 minims a day was reached. He found that there was no objection to the taste of the drug in this combination, and that when the larger doses were reached the effect on the temperature and general symptoms was remarkable. Many of his patients passed blackened or greenish urine, but he had never seen any ill effects from the excre-

tion of creosote by the kidney. Our own experience of creosote in very much smaller doses is certainly widely divergent from that of Dr. Beale. In the first place the weight of evidence is strongly opposed to the effectiveness of creosote in phthisis being due to its germicidal properties, and we conclude that it is with this end that such large doses were employed. The selection of the beechwood creosote is nowadays a universal precaution in administering the drug, as the coal-tar preparations are little else than crude carbolic acid. We have also found a very strong dislike to the taste of creosote administered in cod-liver oil, and many patients who will take the oil readily will refuse it when tainted with creosote. It has always seemed to us that creosote is a most valuable expectorant, and in this way exercises a sedative influence on the cough. Inhalations seem to conduce best to this end, but it is a matter of small importance how the drug is given, as it is freely eliminated by the respiratory mucous membrane. Given by the mouth in doses of more than two or three minims at a time it has seemed frequently to irritate the stomach, and has not in our hands been so beneficial to the gastric disorder of phthisis as is the glycerin solution of carbolic acid. It is hardly conceivable that doses of 180 minims can exert a less irritant effect on the stomach than doses of a few minims, and in pulmonary tuberculosis it is recognized on all hands that the stomach commands the situation in prognosis.

A month or two ago we called attention to a valuable clinical survey of the Posterior Simple Basic Meningitis in Infants by Dr. Carr, and now further light has been thrown on this interesting disorder by Dr. Still from the side of bacteriology. He regards the condition as a specific inflammation of the meninges due to a microbe that is prevalent both in England and America, with its period of maximum activity in the spring of the year. The microbe may be discovered either in the meninges or in the fluid of the cerebral ventricles. It is a diplococcus, smaller than Fraenkel's diplococcus, and closely resembling the gonococcus; it may be found either free, or intracellular. It is best stained with a saturated solution of aniline blue, but does not stain by Gram's method. It is readily cultivated on agar, gelatin agar, blood agar, or in broth or milk, but unlike the pneumococcus it does not coagulate milk. It will not grow at the ordinary temperature of the atmosphere. Dr. Still is disposed to regard

the microbe as identical with the diplococcus intracellularis of Weichselbaum. Experimental inoculations into animals were attended with negative results. The microbe had not been found in the blood, but as periarthritic trouble sometimes complicates these cases it is not improbable that we have then to deal with metastasis from the meninges to the joints.

The Asylums Committee of the London County Council is to be congratulated on the outcome of its appointment of a pathologist, and the equipment of a laboratory suitable for research work in connection with the Claybury Asylum. From this vantage ground Dr. Mott has already thrown some light on the symptom complex of general paresis. He has demonstrated the very frequent presence of fatty degeneration of the muscles, and this without any apparent degeneration in the corresponding nerves. He considers that we have to deal with a toxic principle in the blood due to the degeneration and disintegration of nerve cells, and that this acts as a poison to the motor end plates or to the muscles themselves. Cholin has been found in the cerebrospinal fluid in general paresis, and is known both to be a product of the disintegration of nervous tissue and also to have a paralyzing action on muscle. Mott suggests that the syphilitic poison predisposes to general paresis by lowering the resisting powers of the nerve elements, so that they degenerate more readily when any stress is thrown on them by worry, excess, and the usual excitants of general paresis.

---

#### PARIS LETTER.

---

BY A. R. TURNER, M.D. (PARIS).

---

In my last letter I spoke of the case of Dr. Laporte, who had been imprisoned previous to trial on the charge of having caused death in a case of midwifery by the unskilful use of an instrument employed to perform craniotomy.

At the trial Dr. Pinard, professor of clinical midwifery at the Faculty of Medicine, testified in the strongest terms in favor of Dr. Laporte, declaring that he had done all that could be done, and that his conduct had been admirable. In Dr. Pinard's opinion the lesions found in the bladder were caused by the long-continued pressure of the fetal head. Notwithstanding such testimony Dr. Laporte was condemned to three months in prison,

but with the application of the Béranger law, which means that as it is a first offense the sentence is not carried out. The internes of the Paris hospitals have addressed telegrams or letters of thanks to Professor Pinard for his efforts in this case, and several subscriptions have been started among physicians in favor of Dr. Laporte. The latter has likewise signed an appeal against the decision of the court, which was not the work of a jury, but of a police magistrate.

In addition to the quarantine stations in the Red Sea there exists at Bassorah, in the Persian Gulf, a station intended to protect Europe against cholera or the plague coming from Asia by that direction. As this quarantine station, which is the only one in the region, is under the control of the Turkish authorities, *La Semaine Médicale*, of Paris, has just published an article giving an account of what was observed by a special correspondent whom they had charged with the inspection of the station, but who was not to disclose his profession of physician.

The building used contains five rooms on the ground floor, opening on an inner court of about 100 square meters in area. As no arrangements for food have been made by the health authorities, travelers are obliged to hire a cook, who necessarily comes into contact with the servants of other travelers. But one guardian of the station exists. The inhabitants in the neighborhood frequently come into the station, and worse than all, the soiled clothes of the inmates are carried to Bassorah to be washed. It is unnecessary to comment on such a condition of affairs.

Dr. Cavazzani, surgeon of the Civil Hospital of Venice, recommends the treatment of phlegmonous inflammations by means of one-per-cent. solutions of potassium oxalate, injected into the tissues around the focus of the affection. The first case was a woman who for two months had suffered from a phlegmon of the hand, forearm, and lower portion of the arm. Though the acute stage of the affection was over, the limb was still stiff, red, swollen, and painful. Ten injections of a one-per-cent. potassium oxalate solution were made along the entire length of the arm, two cubic centimeters altogether being injected. Considerable improvement was to be noted the next day, and a complete recovery was obtained in three weeks, the injections being made every three or four days. Two female patients suffering from phlegmasia alba dolens recovered—one after ten to twelve injections repeated twice, the other

after the same number of injections repeated thrice. A case of inguinal phlegmon following an operation for hernia recovered after two cubic centimeters was injected in eight different places around the inflammatory focus.

We have so long been accustomed to look upon alcohol as the cause of cirrhosis of the liver that it is not without surprise that we see Dr. Lancereaux state at the Academy of Medicine that after having long held that opinion he had come to the conclusion that only wine-drinkers suffer from cirrhosis of the liver, and that the cause is the potassium sulphate contained in the wine, due to what is called the "plâtrage" of the latter during its fabrication. It may be said that the majority of the members of the Academy of Medicine received the statement with incredulity.

In a severe case of acute dysentery in a man aged twenty-six years, an interne of the Hospital of Montpellier, M. Ardin-Delheil, obtained good results by giving thrice daily an enema of five grammes of antipyrin in 250 grammes of water. For an hour afterwards, the enema having been retained a quarter of an hour, pain was absent, and the patient had no passages of the bowels. The number of stools was much diminished by the treatment, and recovery rapidly ensued.

---

#### BERLIN LETTER.

---

BY JAMES J. WALSH, M.D., PH.D.

---

After a number of articles on the therapeutic results of Professor Koch's new tuberculin, the German medical journals have practically agreed to let the matter rest for a while. As the editors of the *Deutsche Medicinische Wochenschrift* announced some time ago, any definite or final conclusion as to its therapeutic value is impossible as yet. A large number of observations must be made, and these must be controlled by the condition of the patient, not a month or two after the injections, but a year or more after, at least. This desideratum cannot be fulfilled under present circumstances, so that articles on results obtained, favorable or otherwise, must necessarily be lacking in that essential element in therapeutics, finality of results.

After the sad failure of the first tuberculin, with all the disappointment it involved for the profession all over the world, medical minds were in anything but a state of recep-

tivity for the new tuberculin. Here in Berlin, where the disappointment was most profound, this lack of receptivity was especially noticeable. Within a very short time reports of unsuccessful trials of the new remedy were made. The great clinicians at the Charité were almost hasty in announcing that the new tuberculin was no better than the old. It had been made public only three months when the conclusions were reached, which were given as final at the Congress at Moscow.

After all it would seem that the patient five years' work of the great master of bacteriology deserved a less trenchant procedure than this. He and his assistants have been faithfully noting results for a long time, with the lesson of former failure to make them doubly careful in their estimation of improvement noted; yet they were ready to formally give their results to the world, satisfied to try again the judgment of the profession in the matter. The note of medical opinion all over the world has been taken to a great extent from the leaders of medical thought here in Berlin, but there have been some notable exceptions to this rule. From many of the university clinics of Germany came most encouraging reports. From Greifswald, Munich, Königsberg, Doutrelepoint at Bonn, and from Petrusky at Danzig. From foreign sources there was much more said that was favorable than unfavorable. Thus from Moscow, Amsterdam, Turin, London, and even from Paris, there were reports of successes, especially with the external forms of tuberculosis—those in which results are too evident for the therapeutic tendency to self-deception to have a place.

It is so much easier to condemn in the matter of new remedies than to try out the question on its merits that the *facile consensus* of disapprobation can be easily understood; but to any one who has seen some of the results here in the Institute for Infectious Diseases the hasty condemnation cannot but seem an almost criminal anticipation that may delay the use of an important remedy.

No marvelous claims are made for it; no marvelous cures are shown. Where there is an advancing tuberculous process in the lung, where there are already beginning signs of cavity formation, where already the febrile course shows a serious constitutional reaction, there the new tuberculin is considered to have no place in the treatment. Such cases are to be seen under treatment by the new method, but always at their own urgent

request—sometimes with strikingly good results, too; but no claims are founded on their improvement. For the lighter or just beginning cases, where modern exact diagnostic methods catch the disease almost in its very incipency, these are the cases where symptoms are always observed to regress under the use of the new tuberculin. Especially is this true of the cases in which the febrile reaction after injections of the old tuberculin for diagnostic purposes shows the presence of a tuberculous process that may be hidden from all other diagnostic methods.

In such cases the liability to self-deception on the part of an interested observer is of course very great, but the obvious and unquestionable confirmation of these results is the really wonderful improvement effected in lupus and allied conditions. Some of the cases that may be seen at the Institute were of the worst type and in the most advanced stages. Every remedy imaginable had been tried in them for years. The cicatrization process has gone on steadily and persistently since the tuberculin has been used. The visitor does not see the cured cases, but some of the photographs are very convincing evidence of a powerful curative agent at work. It would seem, then, but fair to the master, to whom in other matters we bow unquestioningly, almost, not to condemn his great work untried. The question is an open one, and true medical conservatism will decide it properly in time; but let us not anticipate.

Bottini's method of treatment for enlarged prostate is at present attracting a good deal of attention here. The fact that it is discussed seriously in severe cases of prostatic hypertrophy even by the medical clinicians is a fair index, I think, of how general the interest is in it. Some of the successes reported from it are very encouraging, though of course the reports come mostly from those who are interested more or less personally in having the profession take it up as a recognized surgical procedure. Here in Berlin it has been tried recently in three cases with marked success, where all other means had failed. In two of the cases castration had been done without result; in the third case excision of the middle lobe of the prostate had failed to give relief. All three of the cases were able to urinate of their own accord the day after the operation, and their urinary condition has continued to improve since. Whether the burning of a groove through the dense connective tissue of the hypertrophied prostate is not going to give rise to dense

cicatricial tissue with an inevitable tendency to contract is not yet definitely settled. Operations have scarcely been done long enough to properly answer the question at this time. Meantime the best results reported so far are no better, not even as good as usually follow castration, while the armamentarium for it is highly specialized and costly, and requires considerable practise in its manipulation. The operation is not likely to become generally popular, but like catheterization of the male ureters, it is likely to be the exclusive privilege of the young surgeon beginning his career and looking for something striking and novel on which to report his first set of cases.

Talking of prostatic hypertrophy, there are some serious clinicians here who report good results in its treatment with extract of prostate gland. Just what the principle is on which it is used is a little hard to determine. It looks a little like *similia similibus*, but the fact remains that some insist it should always be given a trial before recourse is had to any surgical means.

Oophorin—extract of ovary—is spoken of, too, for the troubles of the menopause, and whether it be the incidental autosuggestion that is active, some very good results have been reported just in that class of highly neurotic patients whose climacteric is almost as much of a torment to their physicians as to themselves, and for whom therapeutic measures generally are absolutely without avail.

#### THE TREATMENT OF MALARIA.

To the Editor of the THERAPEUTIC GAZETTE.

DEAR SIR: The THERAPEUTIC GAZETTE is before me—the October number—the first copy I ever received, and in looking over its pages I come across something that I have been looking for some time, viz., "The Exact Treatment of Malarial Fevers." I am called in to see many persons troubled with malaria, and am anxious to learn the best method to cure my patients.

From the heading of the article referred to above I expected to find an exact treatment—an accurate or methodical treatment—one which a beginner could follow; but instead I find a complex method. I believe the writer refers to at least twenty-seven drugs, and states that all are good in their place; but quinine is rated first as almost a specific. I do not agree with the writer's treatment of malarial fevers, yet I do believe he gives us some good points as to what to do with a patient who is convalescing.

I was educated in a homeopathic college, and am willing to confess that I cannot cure malaria by the drugs that I was taught would cure that disease, and I am perfectly willing to try anything from any school in order to cure my patients.

If malaria comes from infection from some outward source—a germ—surely we ought to get at some results without trying at least twenty-seven different drugs.

The writer divides the fever into three stages—cold, hot, and sweating. In the first stage a ten-grain dose of Dover's powder is recommended; also the same dose of the same medicine is recommended in the second stage, in which the condition of the patient is directly opposite to that of the first stage.

If malaria is caused by the plasmodium malarix, and as the writer states quinine will kill the germ by saturating the blood, why mention the other drugs at all?

My criticism of the article, more than anything else, is to prove that the essay on "The Exact Treatment of Malarial Fevers" is not an exact treatment; if it was it would be an exact or methodical one, and it is far from methodical. I have studied malarial fevers over and over again; I have followed those writers who claim that quinine is a specific, and others who claim that it can be treated without the use of quinine, and I feel more convinced every day that there is not any specific for the disease. I have treated cases with both small and large doses of quinine, and had no success at all; with others I have successfully cured by the use of quinine alone. I had one case which was interesting to me and may be beneficial to others—that of a man aged twenty-eight years, a factory operative. I was called to see him about one year ago. He had an attack every day in the factory, so that he had to quit work for an hour or two daily. I took out my case and was going to give him quinine, when he told me that he had taken large amounts of quinine without any favorable result. For over one week he had taken some days twenty-four grains, other days forty-eight grains, and had got the drug effect to perfection, yet had what he termed the "shakes" just the same. I gave him calomel to keep the bowels open, and a pill containing iron 1 grain, arsenious acid  $\frac{1}{10}$  grain, three times a day. He has not had a chill since.

Another case, that I could not do anything with until I found that the boy was a cigarette fiend: by stopping the cigarettes and

giving him two grains of quinine before meals and a pill of iron and arsenic after meals for one week a cure was effected.

I am one who believes in quinine, and though in my case it has not been a specific, it is a drug I could not get along without in malarial fevers.

DR. T. E. KIRBY,  
Upton, Mass.

[The writer of this letter, if he will study the excellent monograph on Malarial Fevers by Dr. Thayer, which we reviewed in the November issue of the *GAZETTE*, will soon be convinced that the plasmodium is the cause of malarial fever in all its forms, and that quinine kills this parasite and is a specific. No one has a right to deny the value of quinine for such purposes without being sure that the condition treated is really malaria, nor is he justified in doing so before he has tried it in many cases, nor until he is sure that the drug has been absorbed. If the case cited above was a true instance of malarial fever we believe the large doses of quinine cured the patient even if the so-called "shakes" did continue for a time, perhaps as a "chill habit." The position of quinine as a specific for malarial infection when used properly is so strong from every point of view that the medical man who denies resembles the unfortunate who asserts there is no remedy for any disease. Other remedies than quinine are often useful to relieve symptoms while the quinine is curing the malady and form useful adjuvants to it. We see no reason for believing the second case cited to be one of malaria.—ED.]

#### IMPROVED HEMORRHOIDAL SUTURE CLAMP.

To the Editor of the *THERAPEUTIC GAZETTE*.

SIR: In last February's *GAZETTE* I read an article by Llewellyn Eliot, M.D., describing the Erwin suture clamp for removal of hemorrhoids, accompanied by cut of same. I thought it was what I needed and sent for it. On using it, however, I found it objectionable in two particulars: first, the jaws of the clamp, turning at right angles to the arms, brought the handles to a perpendicular position when applied to the tumor, and between the operator and the tumor, making it necessary to have an assistant to hold them up, besides being in the way of cutting and ligating; second, the shoulders or perforated portion of the jaws are too high, and consequently left too much tissue after cutting

away all that could be enclosed above the clamp, and the perforations being so far apart left a ragged wound and occasionally more hemorrhage than is ever necessary. To overcome these objections I corresponded with the E. A. Yarnall Co., Philadelphia, and suggested making the shoulders one-eighth of an inch high, the perforations one-eighth of an inch apart, and instead of turning the jaws at right angles to secure parallel action of the blades, to use the truss-joint in front of the scissor-joint, and substitute a nut screw for the ring on the handles.

They succeeded in making an admirable instrument, a cut of which is seen herewith.

This enables the operator to remove any pile without assistance, except when chloroform is necessary. With the use of both cocaine and eucaine I have operated on external and marginal tumors without pain, hemorrhage, or assistance, and the wound looks like a whip-stitched line. Of course a general anesthetic should be used when dilatation of the sphincter is necessary, and this is always the case in internal hemorrhoids. To Dr. Erwin, of Walter's Park, Pa., is due the honor of an invention which should do away with the cautery in the removal of hemorrhoids, for as Dr. Eliot says, "it is almost bloodless, there is no sloughing, it heals rapidly, it removes the entire hemorrhoid, and it does not affect the tone or caliber of the bowel."

A. H. TIDBALL, M.D.

GARRETTVILLE, O.

#### COMPLICATIONS DURING LABOR IN A CASE OF PREGNANCY FOLLOWING HYSTEROPEXY.

To the Editor of the *THERAPEUTIC GAZETTE*.

SIR: Mrs. Ida Y., aged twenty-six, occupation housewife, had suffered from dysmenorrhea for several years. One year ago she was admitted to the Jefferson Medical College Hospital, Philadelphia, where hysteropexy, or fixation of the uterus to the abdominal wall, was done.

The retroversion cured and the patient relieved of her troublesome dysmenorrhea, the operation was naturally considered a perfect remedy, especially as the woman became

pregnant three months afterwards. She went on to the term without any serious inconvenience other than the nausea and vomiting were rather excessive. She was first taken in labor November 21, at 10 P.M., and for forty-eight hours her pains were excruciating, the contractions being very ineffective on account of the acuteness and severity of the pain. At 2 A.M., November 23, when I first saw the patient, she was wild with pain, and so restless that even an external examination was impossible.

After consulting with her physician in attendance, a few whiffs of chloroform were given, which enabled us to make a satisfactory examination. The woman had a fair pelvis, the anterior superior spines 24, crests 26, trochanters 31+, right diagonal 22+, left diagonal 22, and external conjugate 21 centimeters.

The first thing observed upon exposure of the abdomen was its peculiar shape, and the development of the uterus entirely upon the right side, the contractions being confined wholly to that side of the uterus, the left side not participating to any appreciable extent in the contractions. The back of the child lay to the right and the head below, heart sounds to the right and below the umbilicus, and the os uteri was dilated to the size of a quarter dollar. The diagnosis of left occipito-anterior position was made.

As the woman was exhausted with her prolonged labor, as the contractions were so exquisitely painful that they were ineffective, and were entirely one-sided, the uterus being adherent to the abdominal walls in the median line below the hysteropexy scar, it was decided to dilate the cervix and remove the child instrumentally.

After etherization she was placed across the bed and the cervix dilated, using first one and later two fingers of each hand. Forceps were then applied and the child delivered in the usual manner.

The child was born with the cord wrapped twice around the neck, the head being quite blue as a result. This cleared up promptly, after respiration was established.

The placenta was firmly attached to the uterus immediately below the line of adhesions between the uterus and the abdominal wall. This made it necessary to deliver the placenta manually, scraping away the adherent membranes with the fingers.

A small perineal laceration was then brought together by four sutures, and the woman cleaned and fixed in bed. Her puer-

perium was normal in every way; highest temperature  $99\frac{1}{2}^{\circ}$ . The perineum united well, and mother and child are happy and well.

This case appears to me to be especially interesting just at this time on account of the frequency with which hysteropexy is now performed. The operation is of relatively recent origin, not difficult in performance, and is at first, and frequently ultimately, brilliant in its results. This makes it very attractive, but it is certain that a great many cases of retrodeviation and prolapse can be cured by minor gynecology, or at least without invading the peritoneal cavity.

I think, therefore, that while the complications in labor following hysteropexy do not contraindicate its performance where less radical methods are not successful, we should bear in mind constantly, and give proper consideration to, these complications before doing hysteropexy.

---

#### *EIGHTEEN CASES OF DIPHTHERIA—NO DEATHS.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: From the beginning I had been prejudiced against the use of antitoxin in the treatment of diphtheria. During the past four years I have treated eighty-six cases of this terrible disease. I know what it means to dread diphtheria, if any one does, having watched over five of six children who passed away in one family, regardless of anything that could be done by myself and the two other physicians whom I called in consultation. I am now satisfied in my own mind that had antitoxin been used the result would have been far different.

In the last eighteen cases I used Parke, Davis & Co.'s antidiphtheritic serum without a fatality. With one child eight months old (laryngeal diphtheria) death seemed imminent; one injection of 1000 units surely saved the infant's life, and it is now well.

Seven of these cases were indeed bad ones. Under any other treatment I have ever used I should not have been surprised had I lost four or five out of the seven.

I now use antidiphtheritic serum in conjunction with Loeffler's solution with the most confident expectation of a satisfactory result, and I cannot say enough in its favor. My patients have all recovered without a single complication save a mild erythema in two cases.

Yours truly,

FRANK BROUWER, M.D.
